PREFACE

This conference publication contains the proceedings of a symposium on Ozone Trend Detectability which was held in Boulder, Colorado, July 28-29, 1977. The meeting was sponsored by the National Aeronautics and Space Administration to bring together experts in the fields of atmospheric science and statistics for the purpose of assessing our ability to detect anthropogenic disturbances in the Earth's ozone layer.

Two specific questions posed were (1) at what level and how quickly can man detect a trend in total ozone using existing data sources, and (2) whether there is any empirical evidence that the predicted depletion in total ozone has already begun. A number of possible error sources, both within the data measurements and in the modeling assumptions, were identified and discussed. In particular, discussion focused on errors which are themselves subject to trends, and an assessment of their significance was made.

The participants recommended that a multidisciplinary team be formed to develop and improve models used for trend detection and to design measurement programs tailored specifically to look for trends. Other recommendations concerning time series models, the Dobson network, and future research are detailed in this document.

SUMMARY OF SYMPOSIUM RESULTS

by

Janet W. Campbell

INTRODUCTION

A meeting of atmospheric scientists and statisticians was held in Boulder, Colorado, on July 28-29, 1977 for the purpose of addressing two questions related to ozone which remain unsettled despite recent assessments by the National Academy of Sciences (NAS) and the National Aeronautics and Space Administration (NASA). They are: (1) How quickly and at what level can scientists detect unnatural changes in the earth's ozone shield? (2) Is there any empirical evidence of the predicted depletion in total ozone? A structured program on the first day focused on the nature of existing ozone data (Session I) and trend estimation techniques currently being used (Session II). The second day was devoted to issue raising, discussion, and debate.

No quantitative, unanimous answer was found to the first question. Opinions of attendees as to the threshold of detectability (minimum change in ozone which one should consider significant) ranged from 1.5 percent, based on a time series analysis of Hill, Sheldon and Tiede (Geophysical Research Letters, January 1977), to approximately 6 percent, based on a conservative summing of several estimates. Because even the minimum threshold of 1.5 percent has not been observed in data sets since 1970, the answer to the second question, generally accepted by those present, is that there is no empirical evidence of a significant change in global total ozone. Some argue, however, that the trends predicted by modelers would be below our detection threshold and thus must not be ruled out.

Discussion and debate centered on three major issues: (1) the predictability of climatological series, (2) whether empirical models can be trusted, and (3) how errors in the Dobson total ozone data impact trend detectability. A number of recommendations for resolving the issues were also proposed. The issues and recommendations will be discussed separately.

ISSUES

The predictability of climatological series.- It is well known and documented by numerous examples that the character of a climatological series (its periodicities, amplitudes, etc.) can change abruptly after many years of stable variation. The reasons for such changes are not always understood. Thus, it would be a mistake to attribute automatically any observed change in global ozone to pollution or other anthropogenic

sources. Some concern seemed to be felt that any strictly empirical method, no matter how sensitive to ozone change, is inadequate because it cannot attribute changes to possible causes. These concerns were mitigated somewhat with assurances from statisticians that their empirical models would only be used as "early warning devices" to alert the scientific community of the existence of a change and the need for further study to determine its cause.

Some felt, however, that the "nonstationarity" of such time series was an insurmountable obstacle since it seriously degrades our predictive capability. The nonparametric approach presented by Marcello Pagano in Session II is of interest in this context. By this technique, a "trend" is said to appear when the capability of a model to predict one time step into the future diminishes significantly. That is, one observes how accurately a model predicts the time series used in its formulation (presumably this is the best it can do), and then one observes its predictive performance when applied to future time series. If this capability deteriorates seriously then a "trend" is said to have appeared in the future time series. Since, by this method, the quality of the predictive model is not as important as its consistency over time, this approach may have appealed to those who argued that no climatological model can be expected to have good predictive capability.

Empirical versus theoretical models.- As in most scientific research areas, the classical controversy arose between empirical methods ("let the observables speak for themselves") and theoretical methods ("any observed behavior must have a theory to explain it"). Many examples were cited by the atmospheric scientists present of other physical processes whose variations are correlated to ozone variations. These included general circulation patterns and pressure fields, stratospheric winds, trade winds, ocean-atmosphere heat transfer patterns, atmospheric water vapor and temperature, energy sloshing and oscillations in the atmosphere, and others. Julius London estimated that between 50 and 100 papers have been published on the subject of correlating ozone to other phenomena. It was agreed by all, including the empirical modelers, that the inclusion of appropriate exogenous variables in ozone models should improve the models' ability to account for natural variability, thus making the models more sensitive to detecting abnormal changes in ozone. A divergence of opinion existed, however, as to how one determines whether or not an exogenous variable is "appropriate." John Tukey warned that two independent autocorrelated time series can appear to be highly correlated. Similarly, Elmar Reiter warned that like or equal periods in two physical processes (e.g., solar sector crossings and stratospheric ozone oscillations) need not imply a causal relationship between the two processes. Thus, one would need to exercise special care in the selection of exogenous variables. How one

decides which exogenous variables to include and how to bring them into a model are problems which, it was generally acknowledged, are difficult and need further study.

Impact of data errors on trend estimates.- One question which plagued many attendees concerns the relative size of the trends one is seeking (less than 0.5 percent per year) compared to the size of known errors in the data. One answer to this which was brought out at the meeting is that the "accuracy" of Dobson data, as a single quantitative measure, is not specific enough to reveal its impact on trend estimation. The impact of data errors depends on the nature of the errors, whether they are biases or random errors, and whether they are stationary or varying in time. Quite a number of possible error sources were identified and discussed. These included instrument problems such as slow drifts in the optical filter wedge, misaligned or nonparallel slits, temperature sensitivities, and stray light in the instrument. Other error sources involve the assumptions used in the data reduction algorithms, such as the assumed constancy of solar irradiance at the top of the atmosphere, the linearity (or flatness) of absorption and scattering coefficients with wavelength in the uv spectral range, and the failure to include other absorbing species which may be present in the atmosphere. Reid Basher made the important point that the only error sources which can seriously endanger trend estimates are those which can show trends themselves. Such error trends can either be mistaken for trends in the ozone when none exist or, if opposite in sign to existing ozone trends, can partially cancel real ozone trends so as to make their detection less likely or even impossible.

RECOMMENDATIONS AND SUGGESTED SOLUTIONS

The numerous suggestions and recommendations which emerged are listed below.

(1) Several changes to the time series models of Hill, Sheldon and Tiede were proposed in order to make them more acceptable to physical modelers.

(a) It was recommended that autocorrelations extending back beyond one year be avoided since these are highly controversial. This adjustment (concession) will increase the residual standard errors and consequently their estimates of the threshold of detectability. According to William Hill, this change is expected to be small.

(b) A suggestion to change the nine stations used as a global network was made on the basis that the ozone series at several of these stations are quite correlated. This objection may not be valid, however, because the method used by Hill, Sheldon and Tiede required only that the residuals of the nine

station models be independent--not that the original data series be independent. Hill and his associates are convinced that the residuals are independent.

(c) Another suggestion was that an exponential trend be estimated instead of a linear trend since the former is what the physical/chemical modelers predict to result from CFM releases. Hill stated that this was, in fact, done and that the results were virtually the same as with the linear trend model.

(2) Two recommendations were made to use the possible enhancement of trend detectability through the inclusion of exogenous variables.

(a) A bibliography on ozone and correlated physical processes should be compiled.

(b) A multidisciplinary team, including both statisticians and atmospheric scientists, should be formed to develop such a model or at least to propose the list of appropriate exogenous variables to be included.

(3) Recommendations concerning the Dobson network/data numbered two.

(a) Serious consideration should be given to the "archeology" of Dobson data records and their recalibration for the purpose of determining low frequency oscillations and possible trends. Since these are the only long-term records on ozone in existence, we should do the best job possible with the interpretation of these series.

(b) Some assessment of the value of a future Dobson network should be made and this value weighed against the resources used to support it. The latter should be made compatible with the former.

(4) Recommendations relating to the data errors also numbered two.

(a) A detailed error analysis should be made in which every important error source is identified, examined for possible trends, and the sensitivity of ozone trend estimates to these errors determined.

(b) Where error sources are shown to have possible trends, these sources should be eliminated or a means of estimating their trends devised. It was suggested that such a scheme will probably include the use of independent instruments and/or measurement techniques (such as those afforded by satellite instruments).

(5) Experiments or analyses tailored specifically to look for trends were suggested. Generally these involve a maximizing of signal-to-noise in a sense. Two specific examples are listed here.

(a) A very promising possibility is to monitor ozone in the 40 to 45 km altitude region. Natural variability is quite small at these heights, whereas CFM-related depletions are expected to be much greater here than in the total column.

(b) Another possibility is to restrict our analyses to a single season such as the summer season during which natural variability is low. This approach would look for trends from year to year in that season. Seasonal effects will be automatically eliminated and natural intra-seasonal variability will be minimized by the choice of season.

CONCLUDING REMARKS

The meeting of statisticians and atmospheric scientists involved in the ozone trend detectability problem was characterized by a spirit of cooperation between the two groups and an expressed willingness to work together to gain answers to the questions posed. Although the physical scientists, in general, still remain somewhat distrustful of empirical methods which exhibit no physical insight, they came to realize, hopefully, that the statisticians using these methods do have physical insight and, therefore, the statistical tools are not being applied blindly.

The statisticians came away with better physical understanding generally and, perhaps, a better appreciation for the fact that the ozone data used in their models are contaminated measurements subject to a number of errors. Those fearful of the errors in Dobson data were assured somewhat that not all errors present serious obstacles to accurate trend estimation. Nevertheless, some errors, specifically those subject to trends themselves, can present serious problems. The recommendation was therefore made to identify and quantify, if possible, those serious error sources and either eliminate them or correct for their presence. Other recommendations involved the careful archeology of Dobson data to make the best use of our major (only) resource for finding trends, the inclusion of appropriate exogeneous variables into ozone models to account for natural variability, and modifications to the time series trend analysis which might make it more palatable to the physically-oriented modelers.

INTRODUCTION

Stratospheric ozone is one of many trace elements found in the band of atmosphere which encompasses the earth at an altitude of 8 to 50 km. Although the concentration of ozone is small (a few ppm at most) it plays an important role in the life cycle on earth. By absorbing nearly all solar ultraviolet (uv) radiation with wavelengths less than 290 nanometers as well as most uv radiation in the 290-330 nanometer region, the "ozone layer" shields the earth from most of the harmful uv radiation. A depletion of the ozone would allow increasing amounts of harmful uv radiation to reach the earth's surface. This radiation could adversely affect plant, animal and human life as well as cause changes in the climate.

The ozone layer is a naturally dynamic system in which ozone molecules are constantly being created and destroyed. Recently, considerable attention has been focused on the effect of human-related activities on the ozone equilibrium. It has been hypothesized that the release of various chemical compounds into the environment, such as anthropogenic halogens, nitrogenous fertilizers, and emissions from subsonic and supersonic aircraft have caused and will continue to result in ozone depletion. Of particular importance is the effect of the release of chlorofluoromethanes (CFMs) FC-11 and FC-12 since these compounds are widely used in aerosol products, air conditioners, refrigerators and urethane foam manufacturing.

Recently a panel of scientists from the National Academy of Sciences (NAS) attempted to quantify the level of the hypothesized depletion of ozone. On the basis of their research, the NAS panel concluded that the continued release of FC-11 and FC-12 at the 1973 rates "...would cause the ozone to decrease steadily until a probable reduction of about 6 to 7.5% is reached, with an uncertainty range of at least 2 to 20%."

Because of the slowness of the decline (0.07%/year with a range 0.02-0.20%/year), half of the hypothesized depletion in total ozone, a measure (in milli atmosphere-centimeters) of the amount of ozone in a column of air stretching through the atmosphere, would be predicted to take 50 years. This is not necessarily true at all altitudes. For example, the changes at 40 km are far larger--perhaps an order of magnitude--than any changes in the more usually measured total ozone.

Total ozone concentrations are currently measured at approximately 80 sites throughout the world. Although total ozone measurements have been recorded as far back as 1926 (Arosa, Switzerland), most recording stations began monitoring ozone in the late 1950s or early 1960s. Generally from one to five observations are made per day using a Dobson-type spectrophotometer or a filter ozonometer, weather permitting.

SESSION I: THE NATURE OF THE DATA

Julius London presented a "tutorial overview" which began with a display the locations of total ozone stations (Fig. 1) and of stratospheric ozone samplings (Fig. 2). The samplings are largely concentrated in three areas--Japan, Europe, and India. Approximately 75% of the total ozone measurements are made with Dobson instruments which offer the best international measurements. If they are well cared for and well calibrated, their accuracy is on the order of a

Figure 1. Location of Total Ozone Stations (1957-1975)

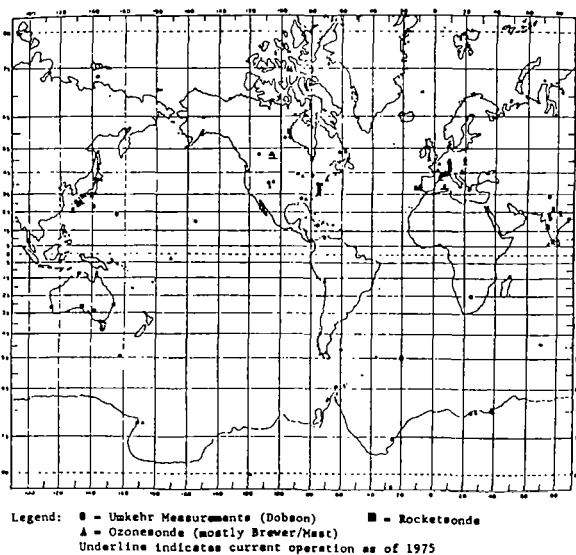

Figure 2. Observations of Stratospheric Ozone (1957-1975)
(non-satellite)

few percent. Long period observations made with the same instrument have "relatively good" reproduction and reliability. The remaining 25% of the world's observations are made with filter instruments which were very noisy until the USSR improved them substantially in 1969. "Now," London said, "they are noisy rather than notoriously noisy."

Plotting the available data produces a picture of global distribution of total ozone (Fig. 3) that shows an equatorial minimum and an increase toward the polar regions. These features of the ozone distribution are both well-known. Variations in total ozone amount depend on season and latitude. This can also be seen in variance data from individual stations (Fig. 4).

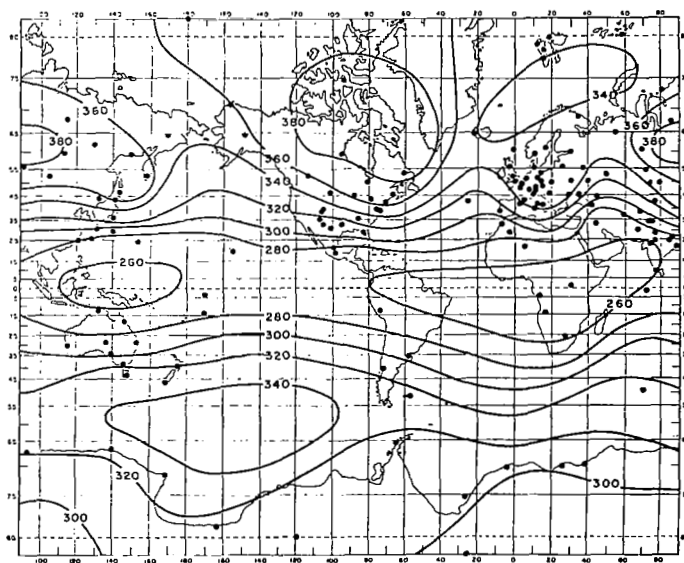

Figure 3. Distribution of Total Ozone for the Period 1957-1975
(m atm-cm)

Although the total ozone pattern is similar in both hemispheres, the northern hemisphere has 3 to 10% more total ozone than the southern hemisphere, not a negligible amount, according to London.

In the stratosphere, the hemispheric difference is even more pronounced as mid-latitude eddy transport is stronger in the northern hemisphere than in the southern. The maximum ozone concentration that occurs in the lower stratosphere varies with latitude and season. (In the summer and at the equator, the maximum is higher than in the winter and at the poles.)

London noted the "close association" between total ozone distribution and pressure distribution in the atmosphere. High amounts of ozone are clearly associated with large scale troughs in pressure distribution.

Figure 4. Seasonal and Latitudinal Variations in the Variance of Ozone Data

Displaying the average latitude seasonal variation (Fig. 5) shows the well-known spring maximum that is stronger in the northern hemisphere than in the southern. This spring maximum is also delayed a month in the south, a fact that London said was "more evidence of the relationship between ozone concentration and circulation" because it reflected the longer relaxation time in terms of the atmospheric circulation.

Figure 5. Average Latitude Seasonal Variation of Total Ozone

Figure 6. Latitudinal Distribution of the Harmonic Parameters of the Ozone Variation

To further reinforce his point that the variance of total ozone concentration is very like the behavior of the lower stratosphere and therefore the result of meteorological parameters, London fitted the mean monthly latitude values of ozone to the first harmonic (annual cycle) and second harmonic (phase) of the annual ozone variance (Fig. 6). Four different comparisons of these data (Fig. 7) then further supported his thesis.

Several statistical scientists commenting on their own efforts to smooth out the seasonal variance noted that: the variance of the reciprocals is less than that of the Dobson data; and nothing really stabilizes the variance although the reciprocal is better than the logarithm.

Figure 7. Comparison between the seasonal variation (monthly mean values) (—), the day-to-day changes within 1 month (February 1973), given by daily mean values (—), possible variation within 1 day (16 April 1962, single readings) (-----), and the differences between mean values of the same calendar month (February) from year to year) (— · —).

Figure 8. Ten Year Running Trend, Arosa, 1932-1973 (monthly means)

London then presented data from a single station, Arosa, Switzerland, where total ozone measurements have been made since 1926. These data (Fig. 8) indicate a long-term change of 6%, about half the standard deviation.

Walter Komhyr presented detailed information about Dobson measurements and the various algorithms used to calculate total ozone. The Dobson spectrophotometer (Fig. 9) takes in light from the direct sun or the zenith sky. The measurement principle requires measuring the ratio of intensities of solar radiation I/I' at pairs of wavelengths, λ and λ' (Fig. 10).

Figure 9. The Optical System

Figure 10. Ratio of Intensities of Solar Radiation I/I' at Pairs of Wavelengths, λ and λ'

Total ozone x is then calculated from the following equation:

$$x = \frac{L_0 - L - (\beta - \beta')mp/p_0 - (\delta - \delta') \sec Z}{(\alpha - \alpha')\mu} \quad (1)$$

where $L = \log(I/I')$;

L_0 is the value of L at the top of the atmosphere;

α and α' are ozone absorption coefficients;

β and β' are molecular scattering coefficients;

δ and δ' are particle scattering coefficients;

μ is the slant path of light through the ozone layer;

m is the air mass;

p and p_0 are mean station pressure and mean sea level pressure, respectively;

and Z is the solar zenith angle.

The ozone absorption coefficients used before 1956 were 36% different from those currently set by the International Ozone Commission (Fig. 11).

*From July 1, 1957, the values of α are based on 1953 results of Vigroux for -44°C, which are about 36% smaller than the values of Ny and Choong used previously.

**Based on coefficients remeasured by Vigroux in 1967 as well as on atmospheric measurements, and recommended for use by the IAMAP.

Figure 11. Dobson Spectrophotometer Wavelengths and Constants

Solution of equation (1) involves dealing with the usually unknown term $(\delta - \delta')$. In practice, therefore, observations are made on double pair wavelengths in which case the particle scattering term becomes $(\delta - \delta')_1 - (\delta - \delta')_2$. To a good approximation, this quantity is assumed to equal zero. The equation for computing ozone using two wavelength pairs is

$$x_{12} = \frac{[(L_0 - L)_1 - (L_0 - L)_2] - [(\beta - \beta')_1 - (\beta - \beta')_2]mp/p_0 - [(\delta - \delta')_1 - (\delta - \delta')_2]\sec Z}{[(\alpha - \alpha')_1 - (\alpha - \alpha')_2]\mu} \quad (2)$$

The most commonly used wavelength pairs are the A and D pairs and this equation is

$$x_{AD} = \frac{(L_0 - L)_1 - (L_0 - L)_2}{1.388\mu} - \frac{0.012mp}{\mu p_0} \quad (3)$$

Values for L , β , β' , α , α' , μ , m , p and p_0 are obtained using laboratory or other techniques. Calibration, i.e., measurements on direct sun, are needed to obtain L_0 . The following equations describe the procedure for calibrating Dobson ozone spectrophotometers on an absolute scale.

Method 1. (Langley Plots). For observations made on clear days when $(\delta - \delta') \approx 0$, equation (1) can be rewritten

$$L + (\beta - \beta')mp/p_0 = -(\alpha - \alpha')\mu x + L_0 \quad (4)$$

which is linear in μ of the form $y = a\mu + b$ provided that x remains constant during the observing interval. By plotting $L + (\beta - \beta')mp/p_0$ against μ (for $0 \leq \mu \leq 3.2$) and fitting a line to the data, the slope is $a = -(\alpha - \alpha')x$ and the intercept is $b = L_0$. In this manner the extra-terrestrial constant, L_0 , is determined for the instrument.

Method 2. (Slope Method). Equation (1) can also be written

$$L_0 - L - (\beta - \beta')mp/p_0 = (\alpha - \alpha')\mu x + (\delta - \delta') \sec Z \quad (5)$$

Let L_0^* be the assumed approximate value of L_0 , L_0 be the true value, and define $S = L_0 - L_0^*$. Then the equation

$$\frac{L_0^* - L - (\beta - \beta')mp/p_0}{\mu} = \frac{-S}{\mu} + (\alpha - \alpha')x + (\delta - \delta') \frac{\sec Z}{\mu} \quad (6)$$

is linear in $1/\mu$. Plotting the left hand side of equation (6) against $1/\mu$ gives the slope $a = -S$, and the intercept is $b = (\alpha - \alpha')x + (\delta - \delta')$ for $\sec Z \approx \mu$. The estimate of S is then used to correct the estimated L_0 value.

The primary standard Dobson spectrophotometer (instrument #83) was used as a reference instrument for a World Meteorological Organization-sponsored International Comparison of Dobson Ozone Spectrophotometers Meeting held in Boulder, Colorado, August 8-19, 1977. Regional secondary standard instruments from Australia, Canada, East Germany, Egypt, Japan, the United Kingdom, and India were compared with reference instrument #83.

A summary of similar instrument comparisons held in the past was presented by Komhyr (Fig. 12).

Figure 12. Results of Past Dobson Instrument Comparisons

Komhyr then presented data on additional absolute calibrations of U.S. standard spectrophotometer #83 that were made in 1962 and 1972. He also presented an analysis of the data which illustrated a method whereby possible variations in L_0 values for the A, C, and D wavelength pairs may be detected. Such variations, for example, may occur with variations in sunspot numbers.

Komhyr concluded his presentation by examining the effect of possible changes in L_0 with time on the accuracy of ozone measurements. He examined three cases:

Case 1: Single pair wavelengths A, B, C, D

$$x = \frac{L_0 - L - (\beta - \beta') \text{ mp/p}_0 - (\delta - \delta') \text{ sec } Z}{(\alpha - \alpha')_\mu}$$

$$\Delta x = \frac{\Delta L_0}{(\alpha - \alpha')_\mu} \quad \text{where} \quad x_{\text{true}} = x_{\text{meas.}} + \Delta x$$

- • If L_0 increased during the 1960's, measured O_3 amounts were too low.

Assume:

$$\Delta L_0 \text{ 1976-1962} = 0.015 \text{ and } x = 0.300 \text{ cm.}$$

Then using:

$$\Delta x_A = \frac{0.015}{1.748\mu} \quad \Delta x_C = \frac{0.015}{0.800\mu} \quad \Delta x_D = \frac{0.015}{0.360\mu}$$

% Error in x			
$\mu \backslash \lambda \lambda$	A	C	D
1	2.9	6.2	13.9
2	1.4	3.1	7.0
3	1.0	2.1	4.6

Case 2: Double pair wavelengths AD, CD

$$x_{AD} = \frac{L_{OA} - L_{OD} - L_A - L_D - [(\beta - \beta')_A - (\beta - \beta')_D] \text{ mp/p}_0}{[(\alpha - \alpha')_A - (\alpha - \alpha')_D] \mu}$$

$$\Delta x_{AD} = \frac{\Delta L_{OA} - \Delta L_{OD}}{[(\alpha - \alpha')_A - (\alpha - \alpha')_D] \mu} = \frac{\Delta L_{OA} - \Delta L_{OD}}{1.388 \mu}$$

Assuming that for the time interval 1962 to 1976

$$\Delta L_{OA} = 0.0154 \quad \Delta L_{OD} = 0.0141 \quad x = 0.300$$

$$\Delta x_{AD} = \frac{0.0013}{1.388 \mu}$$

% Error in x_{AD}	
$\mu = 1$	0.3
$\mu = 2$	0.2
$\mu = 3$	0.1

Komhyr pointed out that if it is assumed that solar irradiance variations occur exponentially in the uv region of the solar spectrum, then errors in total ozone measurements resulting from L_O variations are insignificant when observations are made on double pair wavelength such as the AD pair which is the usual practice. However, observations made on single pair wavelengths could be significantly in error.

Case 3: CC' Observations

These are ozone observations made on the zenith sky using C wavelengths.

For $\Delta L_{OC} = 0.015$ and $x = 0.300$

% Error in $x_{CC'}$	
$\mu = 1$	4.0
$\mu = 2$	2.7
$\mu = 3$	2.0

Thus the errors in CC' observations due to solar intensity variations in the uv region of the solar spectrum can be appreciable.

Reid Basher then discussed systematic errors in Dobson measurements. He pointed out that the measurements are always in error to some extent, as a result of such things as aerosol scattering character, other atmospheric absorbing species, stratospheric temperature, instrument temperature, solar zenith angle, and solar spectral irradiance, but he noted that only those with long-term periodicities are important.

Instrument-related errors can be controlled by regular, rigorous calibration, but, in practice, this may be difficult, and not all errors will be known or appreciated. Atmosphere-related errors - attenuation by aerosols, absorption by other species such as SO₂ and NO₂, dependence of ozone absorption on temperature, and variations in the effective mean height of the ozone layer - can conceivably have long-term periodicities. For example, atmospheric particulate loading rises sharply with volcanic activity and decays with a relatively long half-life. These variable error sources will probably need to be monitored simultaneously in order to attain a high ozone trend detectability.

Basher selected as an example the case of atmospheric aerosols, particulates, and absorbers, explaining as follows:

Since the measurement between a pair of wavelength bands is a differential one, only relative effects are important, e.g.:

$$\log \frac{I_1}{I_2} = \log \frac{I_{01}}{I_{02}} - \mu \times (\alpha_1 - \alpha_2) - m (\beta_1 - \beta_2) - \sec Z (\delta_1 - \delta_2)$$

Consider the effect of aerosol attenuation. If the effect is spectrally flat, $\delta_1 = \delta_2 = \delta(\lambda_0)$, it is eliminated directly within a band-pair measurement. If it is spectrally linear, $\delta_1 = \delta(\lambda_0) + g_1(\lambda_0 - \lambda_1)$, a third wavelength band or second band-pair is needed to eliminate the error.

For a quadratic dependence, $\delta_1 = \delta(\lambda_0) + g_1(\lambda_0 - \lambda_1) + g_2(\lambda_0 - \lambda_1)^2$, four wavelengths or three band-pairs are needed to eliminate the error. The standard Dobson measurement, χ_{AD} , is a two band-pair measurement and thus deals effectively with spectrally linear effects (due to aerosols or other absorbers), but it will be in error if the effects are spectrally non-linear (Fig. 13).

Figure 13. Atmospheric Aerosol and Total Ozone Measurement

Experimental measurements of atmospheric extinction indicate that sometimes there are significant spectral nonlinearities, with $g_2 \sim 4 \times 10^{-5}$, and consequent errors in χ_{AD} of 5%. There is no firm agreement on this problem, since the experimental determination of g_2 is not very accurate, and theoretical calculations indicate that rather unusual types of aerosols are needed to produce the nonlinearities. The effect might well be due to an absorbing species.

One species which does absorb in the uv is NO_2 . Fortunately, its absorption spectrum is reasonably linear so that its error component is largely eliminated by the double wavelength pair λ_{AD} measurement. For a single wavelength pair, though, errors of many percent can arise where NO_2 concentrations are high, e.g. 40 ppb averaged over an atmospheric column. Typical values are 1 - 10 ppb, according to Basher. Further study is needed to assess the spectral non-linear extinction of aerosols and atmospheric trace species, as well as the long-term variability of the spectral character.

Basher then discussed a model of stray light (Fig. 14) that indicates a possibility of errors of several percent in the Dobson instrument, "always an underestimate." The error arises from the interaction of instrument and atmosphere, and is dependent on the instrument's sensitivity to the stray light, as well as the solar zenith angle and the atmosphere's ozone content. The instrument dependence can change slowly with time so a regular monitoring or correction of stray light is needed to avoid giving the appearance of long-term change in ozone. However, Basher concluded, the dependence of the stray light error on zenith angle and ozone itself simply adds an extra amplitude to the already existing yearly cycle term and is thus of no consequence.

Examining the case of calibration errors, Basher noted that calibration basically consists of ensuring constancy in the wavelengths of the bands and determining each band-pair's relative spectral output in the absence of the atmosphere, that is, determining extraterrestrial constants. The first part involves simply a comparison with some stable wavelength standard. From the point of view of trend detection it is desirable to do this at least once a year. Quite rough wavelength calibrations would even be acceptable if they were made frequently and the "roughness" were random. The second part of the calibration is probably the most difficult aspect of ground-based total ozone measurement. For such measurements the "absence of the atmosphere" can only be gained indirectly, and the field measurements involved are time consuming and give inconsistent results that reflect as much as several percent variation in ozone measurements.

Basher reinforced Komhyr's point that the solar near-ultraviolet relative spectral irradiance may not be constant. For trend analysis, extraterrestrial constants need to be constant but not necessarily accurate. The instrument component of the constants can be calibrated with standard lamps, although past experience has shown this to be no easy task. The measurement of the solar uv component of the extraterrestrial constants requires an extra-atmospheric instrument location. The stability of this calibrating instrument must be better than the suggested 0.3% per year sensitivity of the ozone

Figure 14. Model of Stray Light Error in Dobson Total Ozone

trend detection method; that is, it must be stable to less than 0.2% per year in relative spectral response. Moreover, there must exist means to independently verify the stability on a continual basis. Basher said, "The fact that at present such long-term stability is very difficult to achieve, even in the laboratory, should not completely discourage the consideration of preliminary remote space experiments."

In conclusion, Basher noted, "Our present lack of knowledge of the effects of aerosol attenuation and of other absorbers on the ozone measurement and our lack of certainty about the extra-terrestrial constants' constancy severely limit our ability to interpret measured trends as real ozone variation. It is quite possible that aerosols have no significant effect on X_{AD} total ozone, that the uv solar spectrum is particularly constant, and that the 0.3% per year detectability limit is meaningful. However, until we can prove these things we must accept a large uncertainty in trend detection results, probably more than 1% per year. Of course a good deal more study of systematic errors is needed."

Donald Heath next discussed satellite measurements of ozone using the nadir-looking BUV (Backscattered Ultra-Violet) instrument on NIMBUS 4, which was launched in 1970. This instrument is producing data at what Heath termed a cost of "about a dollar each over the life of the satellite, including original cost" (Fig. 15). NIMBUS G planned for 1978 as well as the TIROS N series may carry similar instruments.

The BUV instrument measures the ultraviolet solar radiation which is backscattered by the earth and its atmosphere and compares this, at varying wavelengths between 2550 and 3400 angstroms, to the incoming uv radiation (Fig. 16). The data are used to estimate both vertical profiles of ozone down to the 0.2 millibar level and total ozone. The data inversion technique requires a statistical quantity for P^* , the pressure height of the maximum ozone level as a function of latitude and season. Balloon and rocket data help provide upper and lower first guesses (Fig. 17).

So far total ozone data have been released for the first year of the satellite's mission and these data are currently undergoing a revision based on improved calibration of the instrument.

"We need guidance to determine long term instrument performance," said Heath. He then went on to discuss the puzzle of knowing which Dobson instruments to use for ground truth. Integrating data over the whole globe, he compared BUV and Dobson measurements.

Figures 18 and 19 display two data sets from satellite observations. The massive solar proton event of August 4, 1972, is seen dramatically in a cavity in the ozone formed over the North Pole that persisted for at least two months. This same effect was not observed in the southern hemisphere, probably because it was winter and the ozone variability was very high.

Heath concluded that NASA's primary interest is in the stable high altitude observations where any effect of CFMs should show up. Figure 20 shows NASA's March 1977 assessment of the percent change in ozone due to CFMs.

John Gille briefly described his Limb Radiance Infrared Radiometer (LRIR) results with a special note on the difference between accuracy and precision. The LRIR receives radiation from a 200- to 300-km-long path through the atmosphere. Cold space behind the earth's limb eliminates any problems with back-ground radiation and the ray path eliminates interference from any lower atmospheric regions. The LRIR produces vertical ozone distributions from 15 to 55 kms, as well as temperature distributions (15 to 70 km). Water vapor profiles are expected in the future.

Gille stated that the LRIR accuracy is comparable to that of other instruments including the optical rocketsonde, the chemiluminescent sonde, and the balloon ozonesonde. As to precision, he noted that the LRIR instrument could get a reading every 25 km or 12 to 15 profiles every 4° of latitude. The standard deviation for a single profile is a function of altitude, but ranges from about 1% at 30 km to 3% at 40 km and 10% at 48 km. He noted that comparisons between LRIR and Limb Infrared Monitor of the Stratosphere (LIMS), to be launched in 1978, would provide a very sensitive test of variations at 40 km. For accuracy, he noted that the rms agreement with the chemiluminescent rocketsonde was 10%, about the stated accuracy of the rocket measurement.

James Lovill described the Air Force defense meteorological polar orbiting satellite which can send 68,400 observations a day to the Satellite Ozone Analysis Center (SOAC). Twenty-three Dobson stations in 13 countries have agreed to provide special ground truth measurements to the SOAC to use with the satellite data.

Detailing the measurement procedure, Lovill explained the instrument, its flow diagram, some specific instrument parameters, and the sensor scan geometry (Fig. 21). He then presented satellite readings (Fig. 22), contoured them over the globe (Fig. 23), and provided Arosa readings for July 1977 (Fig. 24) as an example of the ground truth measurements. He concluded his presentation with a display of correlation coefficients vs. distance for two sets of total ozone stations (Figs. 25 and 26).

SESSION II: ESTIMATION OF TRENDS

William Hill, a statistical scientist, began his presentation with an illustration of ozone depletion curves predicted by the findings of the NAS (Fig. 27). In curve A, CFMs are assumed to be released at 1973 rates until some point in time where it is assumed that the releases are suddenly halted. The theory underlying curve A suggests that even after the release of CFMs is ended, a reduction in ozone will continue for approximately 10 additional years before the ozone gradually begins to return to its previous level.

Curve B illustrates the predicted depletion where it is assumed that CFMs are released at 1973 rates without interruption. By varying the rate constraints underlying the chemical reactions involved in the ozone destruction mechanism, a family of curves similar to A and B is produced.

Figure 27. Ozone Depletion Curves

The application of statistical methods to recorded ozone measurements has an important role in the evaluation of the effect of human-related activities on the environment. Since the effects of a long-term depletion of ozone at magnitudes predicted by the NAS would probably be harmful to most forms of life, it is important to determine whether the leading edge of the hypothesized decline has occurred. Seeking to let the data speak for themselves, Hill created empirical pre-whitening filters the derivation of which was independent of the underlying physical mechanisms. When the data themselves are in question, statistical analysis can perform a "checks and balances" effort. Hill noted that time series modeling has some distinct advantages. It filters variations into systematic and random parts, errors are uncorrelated, and significant phase lag dependencies are identified. Hill discussed using time series modeling to enhance the capability of detecting trends.

Hill presented an analysis of ozone data using time series intervention analysis to determine whether the predicted decline has occurred in ozone. He first examined existing ozone data to determine whether a significant global abnormal trend--any positive or negative trend, man-made or natural, which cannot be explained by past ozone data records--has occurred as predicted in the ozone level in the 1970s. The second objective of Hill's analysis was to quantify the potential detectability that could be provided by future

monitoring of ozone concentrations through a global network of recording stations. Detectability refers to the smallest abnormal trend that would have to occur in the ozone measurements to be judged significantly different from zero trend. Early warning of a trend followed by correction of the cause would lead to the return to normal ozone levels (Fig. 28).

Hill presented plots of monthly total ozone values recorded at three sites: Tatenoe, Japan (36N, 140E), Mauna Loa, Hawaii (20N, 156W), and Aspendale, Australia (38S, 145E) (Fig. 29). Many characteristics of total ozone data are illustrated in these plots. The mean ozone levels increase as the distance from the equator increases. The amplitude of the seasonal variation exhibits a similar latitudinal dependency. Figure 29 also illustrates the phase difference in the ozone peaks between North Temperate and South Temperate Zone stations. One predominant characteristic of ozone data which is not obvious from this illustration is the strong seasonal and latitudinal dependency of the month-to-month variance of ozone concentrations.

Since ozone recording stations are not uniformly distributed around the globe, the close proximity of many of the stations casts doubt on the independence of the data records. Thus Hill selected a representative global sample of stations for analysis, a sample in which no particular region has a larger influence than any other region, by dividing the globe into nine equal areas (dark lines in Fig. 30) such that each area contains at least one active recording site with at least 10 years of continuous data. One station with no more than two missing values was chosen for analysis in each area. All data were recorded using the same type of instrument, and missing values were estimated by a graphical linear interpolation procedure.

Figure 28. Hypothesized Ozone Depletion Profiles. Profile A: CFMs released at constant rate until some point in time at which all emissions are assumed to be curtailed. Profile B; CFMs released at constant rate without interruption.

Figure 29. Mean Monthly Total Ozone Measurements Representative of the North Temperate (a), Tropical (b), and South Temperate (c) Data

The stations chosen for analysis using the above criteria are listed in Table 1 and are indicated by the large dots in Figure 30. Since ozone measurements were not made at Kodaikanal in May and June 1975, Hill truncated the series at April 1975. Other missing values occur prior to the period of hypothesized trends, and estimates of these missing values would be expected to have a small effect, if any, on the results.

Hill noted that while the global sample of stations was not truly a random sample of ozone recording sites, the restrictions did not compromise the results of the analysis.

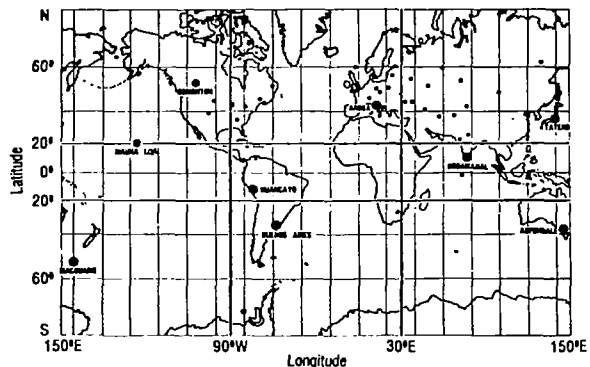

Figure 30. Stations Selected for Global Analysis of Total Ozone Data

Table 1. Stations selected for global analysis of total ozone data.

ZONE	STATION	LOCATION	PERIOD	MEAN LEVEL	# OF MISSING VALUES
North Temp.	Edmonton	54N, 114W	7/57-12/75	357	0
	Arosa	47N, 10E	1/57-12/75	333	2

	Kodaikanal	10N, 77E	1/61-4/75	261	0
South Temp.	MacQuarie Isl.	54S, 159E	3/63-12/75	340	0
	Buenos Aires	35S, 58W	10/65-12/75	288	0
	Aspendale	38S, 145E	7/57-12/75	320	0

The ozone change, or trend, analysis is an application of the intervention analysis technique described by G.E.P. Box and G. C. Tiao in the Journal of the American Statistical Association in 1975. Intervention refers to the occurrence of a phenomenon (man-related or natural) which could possibly affect the level of a time series of data.

Hill's intervention analysis of ozone data attempts to determine whether a change exists in each of nine univariate series that would support the theory of a hypothesized depletion in ozone due to CFMs and other ozone depletion sources. Although the analysis can be completed in one step, Hill broke it into two steps so that the changing month-to-month variance of the ozone data can be more easily incorporated into the analysis.

In this analysis, time series models are first identified. One of the main reasons small trends can be detected is that there is a variance reduction capability in time series modeling. Tukey noted that Hill's "major output is standard errors because that will be most useful in trend detection." This is graphically illustrated (Fig. 31) using the monthly ozone data from Tateno, Japan.

RESULTING TATENO TIME SERIES MODEL

$$Y_t = \frac{(1 - \theta_{12} B^{12}) A_t}{(1 - \phi_1 B - \phi_2 B^2)(1 - B^{12})} = [\text{FILTER}] \times [\text{ERROR}]$$

where

- Y_t = total ozone observed in month t
- A_t = random uncorrelated noise (error) in month t
- B = backshift operator such that $B^{12}Y_t = Y_{t-12}$
- ϕ_1, ϕ_2 = autoregressive parameters representing dependencies between ozone values 1 and 2 months apart, respectively
- θ_{12} = seasonal moving average parameter

rewritten

$$Y_t = Y_{t-12} + \phi_1 (Y_{t-1} - Y_{t-13}) + \phi_2 (Y_{t-2} - Y_{t-14}) - \theta_{12} A_{t-12} + A_t$$

(a) Original Data

(b) Annual Cycle Removed - Original Variance Reduced by 68%

(c) Other Systematic Effects Removed - Original Variance Reduced by 87%

Figure 31. Removing the Systematic Variation at Tateno by Time Series Analysis

Removing the seasonal or annual cycle by using 12-month differences, the variance is reduced by 68% (Fig. 31b). By further identifying and removing the significant dependencies that are still remaining (Fig. 31c), the original variance is reduced by a total of 87%. The eventual residual variation is characteristic of random error and has been checked for randomness by tests of significance.

To identify models for Tateno and the other stations such that the data are reduced to random error (a_t), the autocorrelation function which represents the correlations between data (e.g., deseasonalized data) separated by 1, 2, ..., k months is constructed and is examined for meaningful patterns. For Tateno, the autocorrelation function for the deseasonalized data (Fig. 32) is typical of a second order autoregressive model with a seasonal moving average term. When such a model is postulated and the corresponding coefficients estimated (see model in Table 2), Hill obtains the estimated residuals or errors (a_t) shown in Figure 33. Each model was arrived at independently. Discussion at this point included a comment by John Tukey that "nobody can look at an autocorrelation function and tell what's happening."

Figure 32. Autocorrelation Function of "Deseasonalized" Tateno Data 7/57-12/69

Hill reiterated that he is letting the data decide what is significant. Elmar Reiter countered that the "periodicity of the atmosphere varies too much to do this" and further proposed that eigenvalues be calculated for as many stations as possible.

As a check of the independency of the residuals, the residual autocorrelation function which shows no unusual correlations or patterns is generated (Fig. 34). This supports the adequacy of the model and reaffirms the result that the data have had their systematic variation removed, leaving only the random part for estimating the background variance (σ^2) in trend detection calculations.

Hill identified the pre-intervention time series models and estimated parameters for each station using the Box-Jenkins Univariate Time Series computer package developed by D. J. Pack at Ohio State University. This package uses an unweighted non-linear least squares algorithm to estimate the ϕ s and θ s.

Let y_t , $t = 1, \dots, N$ be a set of N observations collected at equal time intervals. Using all data obtained prior to the (hypothesized) intervention, the first step of the analysis is to identify a time series model of the form

$$\phi(B) (1-B^{12}) y_t = \theta(B) a_t \quad t=1,2,\dots,T-1 \quad (7)$$

for each station, where

y_t is the mean monthly total ozone measurements,

a_t is independently distributed

$N(0, \sigma_i^2)$ random errors, $i=1,\dots,12$ referring to the 12 months

B is the backshift operator (i.e., $B^k y_t = y_{t-k}$)

$\theta(B)$ is the moving average transfer function,

$\phi(B)$ is the autoregressive transfer function,

T is the time of hypothesized intervention, and

$(1-B^{12})$ is used to remove the seasonal variation of the monthly observations.

After obtaining estimates $\hat{\theta}(B)$ and $\hat{\phi}(B)$ of $\theta(B)$ and $\phi(B)$ which account for the phase lag dependencies in the data, a linear ramp function is introduced into the model at the point of intervention as the second step in the analysis. The model is now expressed as

$$\dot{y}_t = \{\omega/(1-B^{12})\} \xi_t + \frac{\hat{\theta}(B)}{\hat{\phi}(B)(1-B^{12})} \cdot a_t \quad t=1,2,\dots,N \quad (8)$$

where
$$\xi_t = \begin{cases} 0 & t < T \\ 1 & t \geq T \end{cases}$$

and ω represents the yearly rate of abnormal change in ozone measured in (m atm cm) per year. Rewriting equation (7) as

$$z_{t'} = \omega x_{t'} + a_{t'}, \quad t' = -T+1, -T+2, \dots, -1, 0, 1, \dots, n \quad (9)$$

where $t' = t - T$

$$n = N - T$$

$$z_{t'} = [\hat{\phi}(B) (1-B^{12}) / \hat{\theta}(B)] y_{t'}$$

$$x_{t'} = [\hat{\phi}(B) / \hat{\theta}(B)] \xi_{t'}$$

ω can be easily estimated by linear least squares.

Figure 33. General Methodology

In these series where the variance is not constant from month to month, approximately unbiased but not necessarily minimum variance estimators should be gotten for the ϕ s and θ s. (The transformation procedure of Box and Cox was applied to the original data $[y_t]$ to see if some power or logarithm transformation of y_t led to constant variance in the transformed variable. No variance stabilizing transformation was found. However, this posed no real problem since the main objective was to find nearly unbiased estimators for the ϕ s and θ s which could be fixed when estimating ω in the next step.)

The results of the model identification and estimation are summarized in Table 2 for Case 1, Case 2 and Case 3. The latter

Figure 34 . Autocorrelation Function of the Residuals
(Tateno Data 7/57-12/69)

is the fit for the complete series through 1975 which is needed for later calculations. For each station the identification program suggests the same model for both the shorter and longer pre-intervention series (Case 1 vs. Case 2).

Once the time series models are thus identified and the parameters are estimated using nonlinear least squares and with data first through 12/69 (Case 1) and then through 12/71 (Case 2), then the ramp parameter ω is estimated from data beginning 1/70 to the end of the series or from 1/72 to the end of the series. By proceeding in this fashion the interval 1970-75 is examined for a possible abnormal change due to intervention (as measured by ω) since it is a period often associated with the predicted onset of man-made ozone depletion. Each model is verified by applying tests of significance to the residual autocorrelations. With the exception of Huancayo, parameter estimates for Case 1 and Case 2 exhibit only slight differences. (Negligible terms are left in the model for Case 2 at Huancayo for comparison purposes only.) The results, in general, suggest that the pre-intervention series are long enough to allow for consistent model identification and estimation. With regard to Huancayo, the relatively large change in parameter estimates may be due to the near nonstationarity of the data series as suggested by the large number of autoregressive terms required to reduce the series to white noise. An instrument drift is one possible explanation of the near nonstationary behavior of the Huancayo series. Inspection of the identified models gives some support for a suspected quasi-biennial cycle. (See, for example, Arosa's moving average term of order 25.)

The results of the first step are the input to the second step which involves estimating the abnormal trend parameter (ω) for each series over the period of hypothesized change or intervention. Estimates $\hat{\omega}$ of ω are obtained as the weighted least squares solution to equation (9). Here the emphasis is on obtaining not only an accurate or unbiased estimate for each ω but also a precise estimate leading to improved sensitivity in trend detection. Theoretically, weighted linear least squares will give minimum variance unbiased estimators when there is non-homogeneity of variance.

The weight assigned to each observation in the analysis is the reciprocal of the standard deviation of all data for that month prior to the hypothesized intervention. For example, in Case 1, the weight for Tateno in May 1972 is the reciprocal of

the standard deviation for all May observations for Tateno prior to 1970. By assigning weights in this manner, the weights are not "contaminated" by observations which are potentially depleted. Thus, defining

$$m = 1 + (\text{remainder } t'/12), t' \geq 0$$

and w_1 = January "weight"

w_2 = February "weight"

etc.,

the $\hat{\omega}$ is obtained for each series and case as the least square solution of

$$w_m z_{t'} = \omega w_m x_{t'} + w_m a_{t'}, t' = 0, 1, \dots, n \quad (10)$$

where $z_{t'}$, $x_{t'}$, and t are as defined in equation (9). The standard error of $\hat{\omega}$ is calculated for each station as

$$SE(\hat{\omega}) = \hat{\sigma}^2 (\tilde{X}' \tilde{W} \tilde{X})^{-1} \quad (11)$$

where the elements of the vector \tilde{X} ,

$$x_{t'} = \{\hat{\phi}(B)/\hat{\theta}(B)\} \xi_{t'}, t' = 0, 1, \dots, n$$

(Note \tilde{X}' is the transpose of the vector \tilde{X} .)

\tilde{W} is a diagonal matrix with w_m on the diagonal

and $\hat{\sigma}^2$ is an estimate of the weighted residual variance.

The estimates of ω and the standard errors are presented in Table 3. For both cases, there are four positive estimates and five negative values for ω covering the nine stations. In only one instance, Huancayo (Case 2), is the estimate of ω different from 0 at the 5% level of significance. The large difference between $\hat{\omega}$ (Case 1) and $\hat{\omega}$ (Case 2) for Huancayo suggests that the increase in the ozone level is a recent phenomenon and may be due to nonenvironmental factors such as an instrument drift. Overall, the results summarized in Table 3 suggest that, in the nine stations analyzed, there has been neither a significant change in the ozone level during the 1970s nor a positive or negative tendency.

A global estimate of change in the ozone, $\hat{\omega}_G$, is obtained by averaging the individual estimates of ω . To simplify the calculation of the standard error of $\hat{\omega}_G$, the nine station residuals were assumed to be independent of one another.

Table 3. Estimated values of ω and standard errors measured in (m atm-cm) per year.

(1) Significantly different from 0 at 5% level of significance (2-sided).				
(2) Pooled estimate.				

Hill checked this assumption by studying the cross-correlation coefficients between the residuals for all 36 pairings of the nine series at different lead/lag values. If two stations are independent, the cross-correlation coefficients should have zero mean and show no pattern that clearly denotes a relationship. Hill detailed his tests of the data for independency.

Since not all the series are variance stationary and hence not likely jointly covariance stationary, the cross-correlation analysis is applied to the weighted residuals. It can be expected that the weighted residuals will be approximately white noise. For two

independent white noise series, the 95% confidence limits for the estimated cross-correlation coefficient for a lag of k months are approximately $\pm 2 \times (N-|k|)^{-1/2}$. Figure 35 illustrates a typical cross-correlation function which was observed in the analysis.

A summary of the significant cross-correlations for the weighted residuals is given in Table 4 for up to lead/lag 12 months, a period Hill said is more likely to show a relationship between stations, if one exists.

There are 35 significant cross-correlations out of a total of 900 values, 25 lead/lag cross-correlation coefficients calculated for each of 36 pairings. The observed percentage of significant cross-correlations is therefore 4% as compared with the theoretical 5%, if each series is white noise. Although there are no obvious patterns in Table 4, certain of the significant cross-correlations might indicate either a chemical or physical transport phenomenon. For example, two pairings of tropical stations--Huancayo-Mauna Loa and Kodaikanal-Huancayo--show a positive cross-correlation between residuals of the same month (or lag 0). One of these, the largest cross-correlation coefficient to be estimated in this analysis, is 0.35 between Huancayo and Mauna Loa. Despite the fact that the significant cross-correlations are small in magnitude, these two pairings might be suggesting some relationship between tropical stations where the chemical effects related to ozone production dominate. There is a possibility that both chemical production and physical transport factors may explain these and some of the other significant lead/lag cross-correlations. Regardless, neither the pattern of the cross-correlations nor the proportion of significant values seems to contradict the general assumption of independency.

A further test of independency is obtained by applying the asymptotic approximation formula of Haugh

$$S_M^* = N^2 \sum_{k=-M}^M (N-|k|)^{-1} \hat{r}_{12}(k)^2 \quad (12)$$

Figure 35. Estimated Cross-correlation Coefficients $\hat{r}_{12}(k)$ of Weighted Residuals from Arosa and Tateno Models (fit through 1975). A Positive Lag (k) Represents Tateno Lagging Arosa by k Months. The Dashed Lines are the Approximate 95% Confidence Limits.

where \hat{r}_{12} is the estimated cross-correlation coefficient between series 1 and series 2 at lag(k), and M is set equal to 12. The test statistic S_M^* is compared to the χ^2 distribution with $2M+1 = 25$ degrees of freedom. We would not reject series 1 and 2 as being independent if S_M^* is less than the $\chi^2 = 37.7$ at the 5% significance level. Only four of the 36 pairings have a significant $S_M^* \geq 37.7$. These are Aspendale-Tateno, Buenos Aires-Mauna Loa, Huancayo-Mauna Loa, and Mauna Loa-Tateno. In the two latter pairings, a single cross-correlation dominates the estimate of S_M^* . There is the lag (0) positive cross-correlation between Huancayo and Mauna Loa, and the negative cross-correlation for Tateno lagging Mauna Loa by 5 months. The high S_M^* between Aspendale and Tateno is reflecting

the significant correlations at $k = -9, -8, -6, -3, -1, 8$ in Figure 36 and Table 4. (The negative k means Aspendale lags Tateno.) This may be reflecting some transport pattern of ozone between two stations which have nearly the same longitude and are approximately equal distance but opposite in direction from the equator. The Buenos Aires-Mauna Loa value for S_M^* is largely affected by the cross-correlations at lags 11 and 12 months (Table 4).

In summary, two types of statistical tests have been performed on the cross-correlations of the residuals from all 36 pairings of stations. The proportion of significant results does not appear unusual, nor does there appear to be a dominant pattern that would lead one to reject the net or general assumption of independency. There are, however, certain significant cross-correlation coefficients that could be reflecting ozone production characteristics in the tropics and ozone transport between regions. These cross-correlation coefficients are relatively small, and since they represent a reasonably balanced mix of positive and negative covariances, their additive effect on $SE(\hat{\omega}_G)$ is likely to be slight with $SE(\hat{\omega}_G)$ either being slightly larger or slightly smaller than already estimated.

Thus, an analysis of the cross-correlations of the residual series does not lead to a contradiction of the assumption that the nine station residuals are independent of one another. The individual estimates of the standard error of $\hat{\omega}_i$, $i = 1, \dots, 9$, are therefore combined to provide an estimate, $SE(\hat{\omega}_G)$, of the standard deviation of $\hat{\omega}_G$. That is:

$$SE(\hat{\omega}_G) = \left[(1/9)^2 \sum_{i=1}^9 SE(\hat{\omega}_i)^2 \right]^{1/2} \quad (13)$$

By dividing $\hat{\omega}_G$ and $SE(\hat{\omega}_G)$ by 307, the overall ozone average can be obtained based on the sample of nine stations. To express this as a percent, the estimated abnormal global rate of change per year for Case 1 is $-0.03\% \pm 0.31\%$ (95% confidence limits). For Case 2, the estimate is $0.09\% \pm 0.42\%$. Both results suggest there has been no statistically significant change in global ozone persisting in the 1970's.

Figure 36. Estimated Cross-correlation Coefficients of Weighted Residuals from Aspendale and Tateno Models (fit through 1975). A Positive Lag (k) Represents Tateno Lagging Aspendale by k Months. The Dashed Lines are the Approximate 95% Confidence Limits.

Setting out to check his linear ramp function with a simulation, Hill determined how well the methodology estimates a predicted decline if the decline were moderately exponential (Fig. 28) instead of linear. All ozone data are artificially reduced according to the ozone depletion model proposed by Jesson (Fig. 37). Using the pre-intervention models in Table 2, a new trend estimate, $\hat{\omega}'$ is calculated for each station after the data are artificially depleted and compared to the original. If the methodology is to be appropriate for ozone trend estimation, the differences

$\hat{\omega}_i - \hat{\omega}'_i$, $i=1, \dots, 9$, when expressed as a percentage of the mean level for station i , should be close to 0.11% for Case 1, where 0.11% is the average amount each data series is depleted per year in the intervention interval. For Case 2, the percent difference should be close to 0.13%. The results of the simulation, summarized in Table 5, indicate close agreement between the artificial exponential depletion and the estimate of depletion from the intervention

analysis. These results indicate that the use of the linear ramp function of equation (11) will serve as a good approximation to typical ozone depletion profiles in the 1970s. As a further check on the analysis, each data series was artificially depleted using a linear depletion model. The trend analysis estimated the reduction exactly, as would be expected from the underlying theory.

Pursuing the issue of global detectability afforded by the monitoring of ozone levels beyond 1975, Hill recalled that detectability is defined as the smallest abnormal change that would have to occur in the ozone data to be considered significantly different from zero change. Quantitatively, at the 95% confidence level, this is simply expressed as $1.96 \times SE(\hat{\omega}_G)$. This is converted to a percentage by dividing by 307, the global average of the nine stations and multiplying by 100%.

Since no abnormal trend is found in the period prior to 1975 (Figs. 38 and 39), the models are refitted over the complete data set (Case 3, Table 2). These show no inadequacies such that the identification step had to be redone. Special attention is paid to the ratio: (mean residual)/(standard error) at Huancayo. Since this is not significant, a trend term did not need to be included in the model.

Hypothesized Ozone Depletion Profile
Used In Simulations.

Figure 39. Finding Trend Detectability Thresholds

Prior to calculating $SE(\hat{\omega}_i)$ and hence $SE(\hat{\omega}_G)$ corresponding to an intervention starting at 1/76 and going into the future, consider each term of equation (11). The vector X is a function of the pre-1/76 data and the length of the intervention interval; W^2 , the diagonal matrix of weights, is a function only of the preintervention data, and $\hat{\sigma}^2$ is the only term which depends on the post-intervention data. Assuming the residual variation prior to 1/76 has the same variance structure as after 1/76, then $\hat{\sigma}^2$ can be calculated as

$$\hat{\sigma}^2 = (T-1-(p+q))^{-1} \sum_{s=L+1}^{T-1} W_m^2 (y_s - \hat{y}_s)^2 \quad (14)$$

where T corresponds to 1/76, the point of intervention

p is the number of autoregressive terms in the model

q is the number of moving average terms in the model

L is the maximum back order

and \hat{y}_s is the one step ahead forecast made at time $s-1$ using models of the form in equation (7)

Estimates of detectability for future monitoring periods of 3 to 8 years are presented in Table 6. Column 2 of Table 6 presents detectability estimates based on the sample of the nine stations. The results indicate that an abnormal change of 0.26% per year, persisting for six years (1.56% total), would represent a significant change in the ozone level, if it were to occur. If the monitoring period extended for eight years, a persistent yearly rate of change of 0.21% per year (1.68% total) would be considered significant. Column 3 gives the detectability estimates based on a global network of recording locations equivalent to 18 independent uniformly-distributed sites with residual variation similar to the nine stations analyzed. This "18-station network" can be constructed by including more of the existing ground-based stations in the analysis and/or using satellite data which should be available shortly. Calculations indicate that an abnormal change close to 1% is detectable from the total ground-based network, if such a change were to occur. A combination of data prior to and after January 1976 (e.g., January 1974 - 78) should provide detectability close to the tabulated estimates.

Table 6. Yearly global ozone changes that must persist for p years to be judged statistically significant.

NUMBER OF YEARS	9-STATION GLOBAL NETWORK	18-STATION GLOBAL NETWORK
3	.48%	.34%
4	.37	.26
5	.31	.22
6	.26	.19
7	.23	.16
8	.21	.15

One apparent characteristic of the intervention analysis is that the total detectability lessens as the monitoring interval lengthens. For example, based on the nine stations analyzed, a total change of 1.44% corresponding to 0.48%/year for three years would be significant, while the total change in eight years at 0.21%/year would have to be 1.68% before it could be judged significant (see Table 6). Hill noted that, "intuitively, this is what one might expect. The faster the yearly rate of change, the smaller the total effect needs to be to be judged significant. Very gradual rates of change are more difficult to detect leading to longer elapsed times and greater total changes. A rigorous interpretation lies in the error propagation characteristics of the estimated step function $\{\hat{\omega}/(1-BI^2)\}\varepsilon_t$ with increasing time."

Assuming that the predicted ozone depletion effects for the various compounds are additive, the predicted net global effect is in the range of 1-2% and should by now be large enough to have

produced a detectable change in the ozone level. The fact that the trend analysis shows no significant abnormal change in ozone suggests that, although the depletion theories may be correct, the depletion predictions when treated cumulatively yield a result that appears to be too large.

Hill concluded that, "The detectability analysis indicates that the ozone data provide an excellent basis for future monitoring of ozone concentrations. The effect of the early warning provided by the data is to minimize the impact on the environment of a change in the ozone level due to man-related activity, if such a change were to occur. For example, if FC-11 and FC-12 were to cause a 1.56% depletion in the ozone in the next six years, an estimated maximum depletion 1.5 times greater (factor based on NAS calculations), or 2.3%, would occur and be followed by a gradual reversal to normal, assuming that the cause is identified and controlled. (See curve A, Fig. 28.) Thus, attention could center upon climatic and biological impacts resulting from potential maximum reversible changes of 2.3%. Further calculations indicate that the detection capability can be increased by incorporating additional ground station data and/or satellite data into the monitoring scheme (Table 6, column 3)."

Hill noted his assumptions that the cause or causes of an ozone depletion can be identified and controlled. If future monitoring should reveal a significant change in the ozone level, careful investigation of all potential depletion sources, human-related and natural, would be necessary before a cause could be identified. For example, natural trends could be mistaken for man-made effects if the periodicity of the natural trend is greater than the ozone record. This would be true of some shorter data series where cycles, such as a suspected 11-year cycle, may not be fully identified and accounted for in the time series model. Trends which might have been caused by instrument drift or local phenomena can be verified by comparing the suspicious results with those of neighboring stations for consistency. Thus, knowledge of both chemical and physical processes associated with ozone activity will be necessary to complete a cause-and-effect evaluation if statistical analysis of ozone data reveals a significant change in ozone concentration.

Next, Marcello Pagano, from the State University of New York at Buffalo, presented his methodology for analyzing the data by using the time series of ozone monthly means from the same nine-station network (Table 7) that Hill used. Pagano reiterated that this network serves as a globally-balanced sample of ozone monitoring stations whose time series had no missing

Table 7. Time series of ozone monthly means.

Station and Dates of Observations	Model Method	Ratio of Before and After Mean Square Prediction Errors			Proportion Negative Forecast Errors		
		PRER			NEGER		
		24 mo.	48 mo.	72 mo.	24 mo.	48 mo.	72 mo.
AROSA Jan 58-Dec 75	2	1.47	1.26	1.28	.67	.65	.61
ASPENDALE Jan 58-Dec 75	2	.92	1.09	.80	.63	.69	.54
BUENOS AIRES Jan 66-Dec 75	1	1.14	1.46	--	.54	.54	
EDMONTON Jan 58-Dec 75	2	.96	.89	.88	.38	.48	.43

95% Significance Level						.36 ↑ .64	.38 ↑ .62
PRER., 60		1.70	1.57	1.52			
PRER., 120		1.60	1.47	1.42			

values. The series is also long enough for statistically significant data modeling and parameter estimation.

Analyzing the data consists of dividing each time series into two parts, the earlier part to fit the model and the later part to generate predictors which can be used to judge the difference between the later observations and the earlier. Because of the short length of the ozone series available, Pagano considered three cases of dividing each ozone series into two parts:
 (i) data through 1973 for modeling, 1974-75 data for predicting;
 (ii) data through 1971 for modeling, 1972-75 data for predicting;
 (iii) data through 1969 for modeling, 1970-75 data for predicting.
 These three cases are referred to as data sets 2, 4, and 6, respectively. Data set 2 yields the longest record for fitting the model, and data set 6 yields the longest record for judging the predictors.

The following is taken directly from Pagano's paper, as submitted to the proceedings, with the exception of italicized comments.

Tests for detecting changes in probability distribution and downward trends in time series

When the state of a system is describable by a time series $Y(t)$ of measurements over time, a natural question that arises is to test a hypothesis H_0 that there have been no changes in the probability distribution of the state of that system starting at a specified time t_0 . One approach to testing H_0 , whose rationale has been discussed by Box and Tiao (1976) is as follows: (1) form a data base of values $Y(t)$ at times denoted $t = 1, \dots, T$; (2) fit a statistical model to the time series $Y(\cdot)$, using its values only up to time t_0 where $t_0 < T$; (3) at each $t = 1, 2, \dots, T$, form the one-step ahead forecasts $Y^\mu(t)$ of the value $Y(t)$ at time based on the values $Y(t-1), Y(t-2), \dots$ at immediately preceding times; (4) comparison of forecasts $Y^\mu(t)$ with actuality $Y(t)$ for $t > t_0$ can be used to determine (qualitatively and quantitatively) whether the model for the time series $Y(\cdot)$ fitted to the values before time t_0 describes the probability distribution of the values $Y(t)$ at times after t_0 .

One important diagnostic tool is the prediction error ratio, abbreviated PRER. The mean square prediction errors before and after t_0 are denoted

$$\text{PREDERRBEF}(t_0) = \frac{1}{t_0} \sum_{t=1}^{t_0} \{Y(t) - Y^\mu(t)\}^2$$

$$\text{PREDEERRAFT}(t_0) = \frac{1}{T-t_0} \sum_{t=t_0+1}^T \{Y(t) - Y^\mu(t)\}^2$$

in terms of which we define

$$\text{PRER}(t_0) = \frac{\text{PREDERAFT}(t_0)}{\text{PREDERRBEF}(t_0)}$$

Under the hypothesis that there has been no change in the model, the probability distribution of the statistic $\text{PRER}(t_0)$ is approximately the F distribution with $(T-t_0)$ and (t_0-p) degrees of freedom, where p is the number of parameters used in fitting the time series model.

The statistic PRER is a test statistic for the hypothesis of no model change at time t_0 which is an "omnibus" or "overall" criterion, in the sense that the test does not specify the nature of the change against which one is testing. One should also employ a "specific" test statistic which specifically tests for the kind of change one is concerned about detecting.

To test the hypothesis that there is a (downward) trend in the measurements, one would use the sign-test statistic

$$\text{NEGER}(t_0) = \text{proportion of prediction errors}$$

$$Y(t) - Y^H(t), t > t_0,$$

which are negative

If the process generating the data is stable, then the proportion of negative residuals (actual value $Y(t)$ minus predicted value $Y^H(t)$) should be about 50%. *That is, Pagano commented, "We are just as likely to underpredict as to overpredict."* If the process measurements have a downward trend, then NEGER (the proportion of negative residuals) should be significantly greater than 50%. (If there is an upward trend, NEGER should be significantly less than 50%.) The expected variability of about 50% $\text{NEGER}(t_0)$ when the hypothesis of no model change is true is described by the binomial distribution (with parameters t_0 and 0.5). Under the hypothesis of no model change, a 95% two-sided confidence region for $\text{NEGER}(48)$ is 36% to 64%, and for $\text{NEGER}(72)$ is 38% to 62% (see table 7).

Ninety-five percent significance levels for the value of PRER are approximately 1.70, 1.57, or 1.52, depending on whether the time span being predicted is the last two, four, or six years, and assuming that the degrees of freedom used in estimating the mean square prediction error over the fitted period is 60. For 120 degrees of freedom these thresholds are approximately 1.6, 1.47 and 1.42.

A technical note: inadvertently, instead of $\text{PREDERRBEF}(t_0)$ we computed

$$\text{PREDERRTOT}(t_0) = \frac{1}{T} \sum_{t=1}^T \{Y(t) - Y^u(t)\}^2$$

using the model fitted to the data up to time t_0 . One then computes $\text{PRER}(t_0)$ using the relation

$$1 - \{\text{PRER}(t_0)\}^{-1} = \frac{T}{t_0} \left(1 - \left\{ \frac{\text{PREDERRTOT}(t_0)}{\text{PREDERRAFT}(t_0)} \right\} \right)$$

Methods of time series model fitting

The first step in modeling a time series $Y(t)$ is to consider its level, or means. Since each station clearly exhibits a seasonal pattern (a 12-month periodicity), the monthly means (means of January, February, ..., December, respectively) are first calculated (Fig. 40, Fig. 41). A test is then performed to see if the monthly means can be represented as the sum of a small number of fundamental harmonics; this would achieve a reduction in the number of parameters required to model the mean. Usually the first two harmonics of the period 12 (frequency $2\pi/12$) suffice to model the monthly means by values called the fitted monthly means. The time series is then demeaned by subtracting from each monthly value the fitted mean for that month; the demeaned series is denoted $Z(t)$.

Figure 40. Monthly Means, Original Data

Figure 41. Monthly Means, Seasonal Means Adjusted Series

The first step in modeling $Z(t)$, representing the fluctuations of a monthly time series $Y(t)$ about its fitted monthly means, is to examine the monthly variances; that is the variance of all January values about the fitted mean of January values, ..., the variance of all December values about the fitted mean of December values. Having calculated the monthly variances one would like to test the hypothesis that the variance is constant over the year. Tests of this hypothesis are available only under the simplifying assumption that time series is Gaussian white noise; it is felt that these tests can be used to provide a vague indication, on the basis of which most stations are regarded as having monthly variances which are not constant but vary. *"This correlation," Pagano added, "is exactly what we want--[we want to know] how dependent the future is on the past."* The only stations which we considered whose variances would be regarded as constant are Buenos Aires, Huancaayo, and Kodaikanal.

When the monthly variances are regarded as constant we denote $Z(t)$ by $Z_1(t)$. When the monthly variances are regarded as varying, we form a de-varianced time series $Z_2(t)$ whose value for a given time t is $Z(t)$ divided by the monthly standard deviation for the month corresponding to time t .

For each series $Z_1(\cdot)$ and $Z_2(\cdot)$, we have two cases: the series is either stationary or periodic-stationary. To intuitively define these concepts, denote the series for expository purposes as $Z(t)$; we will model it as an autoregressive scheme (stochastic difference equation whose right-hand side $\epsilon(t)$ is white noise or independent random variables):

$$Z(t) + \alpha_t(1) Z(t-1) + \dots + \alpha_t(m) Z(t-m) = \epsilon(t) .$$

Using a periodically varying filter rather than a static one, it is necessary to determine the filter length. Pagano pointed out that "statistical theory argues for a shorter filter to have fewer parameters, while reality argues for a long filter length."

$Z(\cdot)$ is stationary is equivalent to: the autoregressive coefficients $\alpha_t(j)$ do not depend on t and the variance of $\epsilon(t)$ is constant in t . How many autoregressive coefficients to use is determined by a statistical testing criterion; we consider two criteria which we call CAT and SELECT. $Z(t)$ is periodic-stationary is equivalent to: the coefficients $\alpha_t(j)$ depend only on the month of t , and the variance of $\epsilon(t)$ also depends only on the month of t . In modeling period-stationary time series we consider three criteria for determining how many coefficients to use for a given month (described in methods 6, 7, 8 below).

The foregoing considerations yield eight possible models for the fluctuations $Z(\cdot)$ of a time series $Y(\cdot)$ about its monthly means.

- Method 1: Treat monthly variances as constant, model Z1 as stationary time series, fit autoregressive scheme by CAT.
- Method 2: Treat monthly variances as varying, model Z2 as stationary time series, fit autoregressive scheme by CAT.
- Method 3: Same as method 1, but fit autoregressive scheme by SELECT.
- Method 4: Same as method 2, but fit autoregressive scheme by SELECT.
- Method 5: Treat monthly variances as constant, model Z1 as periodic-stationary, fit autoregressive schemes using order determined in method 1.
- Method 6: Treat monthly variances as varying, model Z2 as periodic-stationary, fit autoregressive schemes using order determined in method 2.
- Method 7: Same as method 6, but fit autoregressive schemes by PCAT for each month.
- Method 8: Same as method 6, but fit autoregressive schemes by SELECT for each month.

The length of ozone time series does not seem long enough to use the model of periodic-stationary time series (methods 5, 6, 7 and 8) because of the number of parameters that need to be estimated. In our detailed data summaries, we report the model fitting results using these methods, but we explicitly consider interpretable only the model fitting results using methods 1 through 4.

To choose the most representative model for an ozone time series, the choice will be made from either methods 1, 3 or from methods 2,4 depending on whether one accepts or rejects the hypothesis that monthly variances are constant.

If one would like to select one of the models fitted as being "best fitting," a principle for choosing a modeling method is the following: choose the method which yields smallest overall mean square prediction error using PREDERRTOT on data set 2, and smallest mean square prediction error over the data set not used to fit the model using PREDERRAFT on data set 6. We believe that the conclusions are essentially similar for all models fitted by methods 1-4, but it seems worthwhile to choose one method as being most representative. The test statistics for this method are reported in Table 7.

Table 8. Autoregressive filter of model fitted to fluctuations $Z(t)$
 $Z(t) + \alpha_1 Z(t-1) + \dots + \alpha_m Z(t-m) = \epsilon(t)$

Table 8 summarizes the coefficients of the stationary autoregressive models fitted to the fluctuation series $Z(t)$ at each station.

Since this methodology should work with any parameter that varies seasonally, London proposed applying the same technique to temperature data to see if the methodology successfully predicts the world-wide cooling that has occurred since the 1940s. If the technique does forecast the temperature change, it would clearly strengthen the methodology and lend greater evidence to the conclusions about other seasonal variations such as ozone.

Conclusions

The values of the test statistics summarized in Table 7 do not reject the hypothesis that there has been no downward trend in the measurements of ozone levels in the period through 1975.

By the test statistic NEGER (proportion of negative forecast errors) Arosa and Aspendale could be considered to have a significantly high proportion in their forecasts over 1971-75, but not over 1969-75. Their values of the test statistic PRER is not significantly high.

The values of PRER for Huancayo are significantly high which indicates a change in the probability distributions of ozone levels; to interpret this one uses the values of NEGER which are just barely significantly low for Huancayo. Therefore, if there is any statistical evidence of trend in ozone measurements at Huancayo, it is an upward trend.

On the other hand, the values of PRER for Macquarie Islands are significantly high, but NEGER is non-significant. Therefore, the ozone measurements at Macquarie Isles might provide statistical evidence of a downward trend. It is the only station with this property. It is also the station for which our time series model fits the worst when one compares the mean square forecast error with the overall variance of the time series (summarized in Table 9).

Table 9. Comparison of mean square forecast errors with overall variance of time series

STATION	MEAN	VARIANCE	MEAN SQUARED FORECAST ERROR PREDERRAFT	
			Last 4 Years	Last 6 Years

Janet Campbell of NASA Langley reviewed the "imperfect data question." She defined the following terms:

$\hat{O}_3(t,x)$ = Dobson measurement

$O_3(t,x)$ = Actual total ozone

where both are associated with a time t and position x . The error associated with this measurement is:

$$\epsilon(t,x) = \hat{O}_3(t,x) - O_3(t,x)$$

In order to determine data quality, one must know something about the properties of $\epsilon(t,x)$.

Campbell showed two data records which were made simultaneously by side-by-side Dobson instruments at Arosa, Switzerland. Since both instruments are attempting to measure the same $O_3(t,x)$, then differences in simultaneous measurements are, essentially, differences in errors. Thus, one can gain some insight into the magnitude of errors at this station by examining these differences.

Writing:

$$\begin{array}{ccc} \text{known} & \leftarrow & \text{unknown} \\ \hat{O}_3(t,x) & = & O_3(t,x) + \epsilon(t,x) \end{array}$$

and noting that the left-hand side of the equation is the known (observable) information and the right-hand side represents an unknown partitioning, then the known average of a set of Dobson measurements is an estimate of the average true ozone plus the average error (bias). That is:

$$\begin{array}{ccc} \text{known} & \leftarrow & \text{unknown} \\ E(\hat{O}_3(t,x)) & = & E(O_3(t,x)) + E(\epsilon(t,x)) \end{array}$$

If $\epsilon(t,x)$ is unbiased, then $E(\epsilon(t,x))$ tends to zero for a "long enough" averaging period. The assumption of no bias may not be reasonable, however.

Trend estimates are limited by the variance of the data, that is, by:

$$\begin{array}{ccc} \text{known} & \leftarrow & \text{unknown} \\ \text{Var}(\hat{O}_3(t,x)) & = & \text{Var}(O_3(t,x)) + \text{Var}(\epsilon(t,x)) + 2 \text{Cov}(O_3, \epsilon) \end{array}$$

It is desirable for the errors to be independent of the actual total ozone (i.e., $\text{Cov}(O_3, \epsilon) = 0$). If this is the case, then

$$\text{Var}(\hat{O}_3(t,x)) \geq \text{Var}(O_3(t,x))$$

and

$$\text{Var}(\hat{O}_3(t,x)) \geq \text{Var}(\epsilon(t,x))$$

so that the known data variance provides an upper bound on the variances of O_3 and ϵ .

To decide about the existence of a bias or whether or not errors are correlated to O_3 , one should "pull the errors apart" and look at potential error sources. Three major causes of error are:

1. incorrect instrument calibration, poor maintenance, etc.
2. algorithms used to convert measured radiances to total ozone estimates
3. meteorological/geophysical variables.

A calibration error, for example, could produce either a constant bias or a time-varying bias (drift) in the data. Correlations between ϵ and O_3 can result from the correlation of both with a third variable such as another atmospheric constituent.

There are some types of errors which can seriously affect trend estimation techniques whereas others are not so serious. An unknown but constant bias will not affect trend estimates, whereas a bias which changes over time can either be mistaken for an ozone trend or cancel a real ozone trend of opposite sign. The actual magnitude of errors is not necessarily a problem because this is accounted for in the trend estimation techniques, provided that the data variance properly reflects these magnitudes. This condition will be met, as discussed earlier, if $\text{Cov}(O_3, \epsilon) = 0$. It is important to examine error sources and attempt to identify or remove the serious errors.

There are two possible mistakes which can be made in our conclusions. The "Type I" mistake would occur if we were to detect a trend which doesn't exist, and the "Type II" mistake would result if we were to fail to detect a trend which does exist. As previously mentioned, errors which contain a trend in themselves could result in either of these mistakes. A Type I error could also result from too short a data record when a natural low frequency oscillation is mistaken for a monotonic trend. A Type II error can result from an inadequate model in which residual variances are too high. The models of Hill, Sheldon and Tiede, with their low trend detectability thresholds, do not suffer from this problem. The major type of data inadequacy which can invalidate their results would be trending errors.

(Campbell noted: "This discussion of errors applies only to situations where one is analyzing time series at one or more stations and making inferences about those stations. Where inferences are 'extrapolated' beyond the stations for which data are available, as for example, a global mean estimated using data from 9 stations, other errors can occur and these are not addressed here.")

Komhyr emphasized the importance of Type I errors where the "net effect could be no trend" and suggested that it might be useful to look at variations in different levels of the atmosphere. He added, "Statistical analysis can tell you if a trend is going on or not, but physical and chemical analysis must explain the data."

Gille observed that the ozone concentration in the 40-km region reflects the first effects of photochemistry. Since the natural variance of ozone concentration is thought to be low at this altitude, it is a good place to look for the first evidence of changes in ozone photochemistry. In addition, the variance in limb scanning data is low at this altitude, giving two reasons for an improved signal-to-noise ratio.

SESSION III.- FORUM FOR DISCUSSION AND DEBATE

The second day was opened by A. Barrie Pittock who made a plea for including physical understanding of sources of variances and the physical processes in the atmosphere. Statistical models looking at the data set without knowing what is going on are likely to be misleading. He cited the classic example of water levels in Lake Victoria which showed two nice 11-year cycles prior to the early 1920s that correlated with sunspots, but then showed much shorter, small amplitude cycles until the early 1960s. A massive rise of more than a meter then took place and levels have dropped only slowly since then.

To illustrate his point that physical insights can make sense of climatic series and provide evidence of causal relationships, Pittock showed a time series of precipitation in Seattle with an apparent anomalous increase in rainfall in the Puget Sound area since 1940. He then showed how this apparent anomaly can be accounted for meteorologically with the location of high pressure. "Thus," Pittock concluded, "we can use one physical time series to account for another."

Pittock pointed out the high variability of atmospheric ozone content, the variance of which changes markedly with altitude (Fig. 42), and showed the results of a recent analysis which broke the total variance in ozone over Aspendale (38S) down into components having different time scales and possible causes (Fig. 43).

Figure 42. Variability of Atmospheric Ozone Content

Figure 43. Components of Variance in Ozone over Aspendale

Noting that spatial patterns of variation give clues to the physics behind them, Pittcock stressed the need to identify regions/stations which should be monitored to understand apparent trends.

In specific reference to Hill's methodology, Pittcock said, "It is not just a matter of selecting equal area boxes but worrying about where the boxes are."

Spatial patterns of mean distributions or patterns of change, or eigenvector characteristic patterns, or patterns of correlations between stations or with circulation parameters can be used.

In eigenvector analysis, usually 80% to 90% of the total variance can be accounted for by the first eight or so patterns. So, Pittcock suggested identifying patterns which account for the variances, then looking for what might cause them.

Pittcock continued, "A few such patterns usually account for most of the variance, leading to physical hypotheses concerning causal relationships which can be tested." The dominant patterns in many climatic variations are standing waves, due to orographic effects and land-sea distribution, and patterns related to the strength of the Hadley circulation. These mechanisms, which operate on ozone, largely account for correlations between stations (Fig. 44) and suggest where monitoring stations should be located. Ozone in the southern hemisphere is highly correlated with the latitude of the high pressure belt (Fig. 45).

Correlations R, between Spring (ASO) mean total ozone amounts between various pairs of Southern Hemisphere stations. N is the number of data pairs, R^2 is the percentage of the variance accounted for by the correlation, and P is the percentage probability that the correlation has occurred by chance.				
STATIONS	N	R	R^2	P
Hobart & Wellington v Aspendale	9	0.85	72	< 1
Macquarie Isle v Aspendale	10	0.81	66	< 1
Amundsen-Scott & Byrd v Aspendale	11	0.77	59	< 1
Brisbane v Aspendale	14	0.73	54	< 1
Darwin v Aspendale	5	0.20	4	large
Argentine Island v Aspendale	8	-0.33	11	large
Darwin v Brisbane	5	0.44	20	large

Figure 44. Correlations Between Stations

Time series of amplitudes of characteristic patterns should be monitored and compared with correlated circulation indices. A breakdown in well-established correlations between ozone variations and variations in other atmospheric parameters or indices would suggest the need to investigate anthropogenic causes.

Hypotheses as to anthropogenic causes should be tested by correlating indices of hypothesized causes, intermediate effects and corollaries, as well as effects on ozone. Pittcock concluded, "If there is a change occurring and there is not a change occurring in the general circulation, then we'd get very suspicious."

Figure 45. Total Ozone Versus Latitude

London presented information that the largest variance occurs with the largest ozone buildup (in winter), not at the largest total amount of ozone, to which Tukey added that "in a system with feedback, arguing with lags is hanging over an abyss because to say it occurs is also to say the reverse is true."

Lovill next discussed a paper, Temporal Variability of Total Ozone During 1957-75, written with his Lawrence Livermore Laboratory colleagues Thomas J. Sullivan and John A. Korver. The paper, as submitted to the proceedings, follows.

There are 152 stations that have taken total ozone observations. The length of record varies from 6,618 days (July 1957-December 1975) with observations taken at Aspendale, Australia to as few as six days at Woomera, Australia. This paper will use only the data from 15 of these 152 stations. The stations were selected on the basis of longevity of record and their individual standard deviation (σ). Each of these 15 stations has a minimum record data length of 18 years. The standard deviation of ozone values at a station is primarily a function of the instrument calibration and daily meteorological variability.

We have calculated the standard deviation of total ozone variations at a subset of 99 stations. These stations are located as shown in Figure 46 (a,b) and their σ 's are indicated in Figure 47 (a,b) and Table 10. It is readily obvious that the σ 's increase in value from lower to higher latitudes. The standard deviations range from as low as 9 m atm-cm at Huancayo, Peru to as high as 108 m atm-cm at Yakutsk, U.S.S.R.

It is worthwhile to compare the σ 's at stations in similar latitude bands in order to obtain an estimation of individual station meteorological variability and instrumental accuracy. The σ 's at stations in North America compare well with those in Western Europe at selected latitude bands. A comparison of the Western European and North American data with those of the Japanese stations also indicates similar values as a function of latitude. However σ 's at many stations in the Soviet Union do not compare well with the data from North America, Japan, and Western Europe. In the southern hemisphere there are considerably fewer stations and the σ variability is large. Two stations do appear to deviate significantly from the average for their latitude band: these are Port aux Francais ($\sigma = 83$ m atm-cm) and Dumont d'Urville ($\sigma = 85$ m atm-cm).

Next we looked at regional total ozone variations during the 18-year period by combining the individual station records for selected regions (Figs. 48-51).

When this is done for the two Canadian stations ozone is observed to increase irregularly until 1966; thereafter it irregularly decreases. The combined record of the three Japanese stations indicates an irregular, slow increase of ozone that is continuing until the present. The two Australian stations indicate an irregular decrease of ozone continuing until the present. The Indian stations show a strong increase of ozone until 1964 and thereafter a slower increase and since ~ 1970 a steady amount.

Next we have expanded our coverage using these 15 stations until it is global in extent. We will look at two different techniques for analyzing these 15 stations, which we think represent the best long-term data record available. In Figure 52 we have plotted the 18 years of data from the 15 stations such that each station contributes equally. These data in Figure 52, which are strongly biased toward the Northern Hemisphere (especially Europe) indicate an increase of total ozone until ~ 1970 and thereafter a decrease. Figure 53 weights the station data in the Northern Hemisphere equally with those from the Southern Hemisphere. In this figure it is very difficult to determine a trend of any significance.

Figure 48. Ozone Variations at Canada

Figure 49. Ozone Variations at Japan

Figure 50. Ozone Variations at Australia

Figure 51. Ozone Variations at India

Figure 52. Ozone Content, Each Station Weighted Equally

Figure 53. Ozone Content, Each Hemisphere Weighted Equally

Both data sets do show a decrease of ozone after ~ 1970 and a distinct minimum in 1961.

It is our conclusion that a carefully selected data set of 15 stations indicates no obvious long-term trends in global total ozone. Because of the data sparsity over the oceanic regions and the strong bias toward the Northern Hemisphere (and especially Europe), we feel that analysts should utilize the total ozone data available with caution and careful inspection of parameters, such as the station σ 's.

SATELLITE ANALYSIS

Figure 54 indicates ~ 100 days of total ozone data as measured by the Nimbus 3 IRIS sensor. These data have been latitudinally weighted to remove areal bias. The data extend through a period starting with the Northern Hemisphere spring (Southern Hemisphere fall) and ending with the Northern Hemisphere summer (Southern Hemisphere winter). The standard deviation for the data set is 2.6 m atm-cm.

During this period there was approximately 5% more total ozone observed by satellite in the Northern Hemisphere (318 m atm-cm) than in the Southern Hemisphere (303 m atm-cm) (Table 11).

Figure 54. Total Ozone Data Measured by
 Nimbus 3 IRIS Sensor

So. Hemis.	302.9	303.1	303.1	8.9	0.2	0.07%
30°N-60°N	337.5	344.1	341.6	14.3	6.6	1.96%

Perry Gluckman presented his time series analysis which was done in the frequency domain rather than the time domain. His analysis tended to corroborate what other speakers had presented. Details of his presentation are not available for the proceedings.

John Tukey of Princeton University discussed the use of exogenous variables. "While I do not for a moment undervalue physical insight or physical explanation, it is important to keep in mind that purely statistical considerations call for making adjustments of empirical size for any internally reliable exogenous variable that could possibly make sense.

"We ought to do more to find and use exogenous variables." He concluded by suggesting some exogenous variables that might help:

- Pittock's general circulation quantities
- Reiter's energy sloshing and vacillation
- Gluckman's intermonth adjustment to fixed dates
- Gluckman's sector crossings - field reversal
- ??? geomagnetic character figures

Others suggested by conferees included:

- local winds aloft
- local barometer
- local height of tropopause

Tukey said, "Suppose we do adjust for the local barometer, then collect the global mean. Then we must think carefully about the interpretation if the mean barometric pattern is changing." London noted that this was already done, at least in part, in Pittock's general circulation.

Tukey summarized his suggestion to "use the things we can trust--such as local pressure--and see what happens when we use them and then look for explanations." London responded that the key problem is the use of extra information in terms of filtering. "You are bringing up the key to the filtering problem in getting the real information." Tukey agreed saying we should "use all available principles of witchcraft and if some are roughly orthogonal we should use both." He restated Hill's methodology as using persistence and shocks to see what they tell us, then focusing the analysis on the shocks. This methodology, Tukey said, "does get you out of certain technical problems; it saves trouble with the data Hill had. If we can provide better data, perhaps he can do better." But Tukey concluded, "We cannot bypass Basher."

James K. Angell, of NOAA, compared ozone trends with stratospheric water vapor, the temperature of the equatorial tropopause, and the north temperate latitude temperature (Fig. 55) to illustrate what he termed some "very interesting" results. Although the water vapor data record is short, beginning in 1964, and there are not many measurements (only one a month at the most), the total ozone is very well correlated with water vapor and distinctly out of phase with stratospheric temperatures. That

Figure 55. Comparison of Ozone Trends with Stratospheric Water Vapor, Temperature of Equatorial Tropopause, and North Temperate Latitude Temperature

is, the maximum ozone occurs when the stratospheric temperature is the lowest, an unexpected result for which Reiter offered a meteorological explanation: stratospheric water vapor comes mostly from summer monsoons whereas ozone is a winter characteristic. He further suggested that the anticorrelation of temperature may be due to pressure distributions as suggested earlier by Pittcock.

Angell expanded the puzzle with Umkehr data (Fig. 56) noting that, "If you accept Umkehr data, we see an increase instead of the expected decrease due to CFMs. This problem is not really resolved but, where we should see a 5% decrease and we see instead 12% the other way, it makes us wonder."

In subsequent discussion Angell pointed out that an anomaly in the data coincides with the eruption of Agung, leading him to question how Hill's analysis deals with such an anomaly. Hill said that he had misunderstood the previous question and that indeed the volcanic effect was in his analysis and that his techniques certainly try to quantify such interventions. Tukey elaborated that Hill's pre-whitening filter says nothing about mechanisms. "The effect of Agung is in there but it is not really significant --the whole question can be solved if Hill leaves out the quasi-biennial and uses only short analyses."

Pittcock agreed that using only short analyses would avoid "the primary problem of building in a prediction that Agung will happen again."

Tukey, attempting again to summarize the issues at hand, said there are at least three parts to the problem--potential measurement troubles as described by Basher, the question of where you measure to gather global meaning, and the statistical factors--and each part "must be got at separately." One must allow for the real world because none of the other factors has yet included any natural trends.

Figure 56. Umkehr Data

Referring to a three-dimensional chemical-dynamical model developed by Jerry Mahlman of NOAA-GFDL, Campbell said this model showed poor agreement when used to compare the "true" global change in ozone to a global change estimated using Angell's best 53 stations placing equal weighting on each of the 53 stations. However, Tukey interjected, "a very different idea" could be achieved by "sensibly weighting the stations geographically." Tukey suggested 1) do a consistent (simplified) time-series analysis (short lags only) for say, 53 stations; and 2) study covariances and perhaps correlation coefficients between estimated shocks, and check the spectra, and some cross-spectra, of the estimated shocks. He recommended as further steps forward: "criticism" of empirical adjustment (regression) coefficients in terms of frequency bands (Fig. 57).

Breakdown of such analyses as

Figure 57. Empirical Adjustment Coefficient in Terms of Frequency Bands

John DeLuisi asked if transformation can be made from historical ozone data to satellite data that, while global, will necessarily have some scatter. It would seem that a reasonable overlap would be at least one solar cycle. C. Desmond Walshaw noted that the Dobson instruments would be needed for some time. "Ozonesondes," he said, "were going to make the Dobsons obsolete and they did not." He continued, "Everyone who uses the total ozone network should be aware that there are all sorts of problems." (Fig. 58).

The Dobson measurements are not only extremely important for the next 10 years but they are equally important as historical records if they can be corrected by "measurement archaeology."

Komhyr noted that the basic problem in making Dobson spectrophotometer observations is the effect of pollution where it is estimated that errors of several percent can result. As far as NOAA's total O_3 data are concerned, we have the basic calibration information that can be used to improve the quality of existing data; however, we do not have the necessary resources to make these corrections.

$$\Delta N = \mu \tilde{\alpha} \Delta x$$

$$\text{Take } \begin{cases} \Delta x = 300 \text{ m atm-cm} \\ \mu = 2 \end{cases} \quad \text{i.e. } \frac{\Delta x}{x} \approx 0.01 = 1\%$$

	C	AD
$\tilde{\alpha}$	0.8	1.4
$10^3 \Delta N$	4.8	8.4

BELSK INTERCOMPARISON 1974

Figure 58. Accuracy of Total Ozone Network (Direct Sun)

THE FUTURE

Figure 59. Worldwide Network

But after the current intercomparisons Walshaw said, "We should have a satisfactory worldwide network for the first time." (Fig. 59)

Joseph Drewry explained that his primary interest was mission analysis. "What future satellite missions do we need to determine total ozone?" he asked.

"It is not obvious that time series analysis can address the ozone problem." Drewry proposed a possible solution of "letting the data develop a global spectral model of ozone in a natural coordinate system, and trying to minimize the variance of important model parameters with sampling analysis." Figure 60 shows the sampling capability of a simulated solar occultation mission over an ozone model based on weekly estimates over a $5^\circ \times 15^\circ$ global grid.

Figure 60. Sampling Capability of Solar Occultation Mission

He emphasized that the difference between the model estimates and estimates from the simulated mission reflects sampling distribution, not measurement errors. Drewry referenced Figure 61 when discussing empirical orthogonal functions as a technique for examining the information in a data set representative of global ozone data. He noted that "in the set of gridded data from which this example was taken, 98 percent of the variability about the monthly mean

Figure 61. Principal Component of Data
 Ozone Spatial Distribution -- October, 1970 Source: Nimbus IV

Figure 62. Balboa Data

can be explained by 6 eigenvectors; almost 85 percent is explained by the first principle component." He cautioned that data used in an analysis such as this could contain systematic errors which would be misinterpreted as ozone variability.

Tukey suggested contouring the next six eigenvalues to get the last 2% and then "looking for the physics behind them, assuming there is some physics behind them."

Glenn Brier presented a point of view as to how ozone helps understand the quasi-biennial oscillation using 26 years of data from Balboa (Fig. 62). He noted that, "If you look at a model with feedback you should expect trends and, in a two-season system, you should get a biennial result." The actual result (Fig. 63) is very asymmetrical with respect to the seasons, yielding a picture of interventions and shocks which are not randomly distributed. Narasimhan Sundararaman mentioned that the high altitude pollution problem led his agency to modify the original question, "Can we find a trend in the ozone?" into a new, more-to-the-point question, "What is the optimum Dobson network that would really give us the trends and how do we get that network?"

Figure 63. Results of Model with Feedback

To get a deeper understanding of the measurement error problems for ozonesondes and Dobson instruments, Heath suggested developing independent measurement checks, and comparing high quality Dobson data with satellite information. Rocket measurements, too, are possible. Although quite difficult, a standard rocket payload has now been developed. The rocket program, begun 10 years ago, should provide information on the total ozone trend by noting a trend in the 40-60 km altitude range.

SESSION IV: CONCLUDING REMARKS

At the conclusion of the Symposium, the chairmen from Sessions I and II were given an opportunity to make summary statements.

Dr. Hill began by thanking the conveners of the Symposium for the opportunity to present details of his time series analysis and the fruitful interchange that resulted. He reaffirmed his belief in empirical methods as "letting the data speak for themselves" rather than interjecting into models preconceived physical mechanisms that may not be supported by the empirical evidence. He conceded that empirical methods can lead to physically meaningless or unexplained results and, therefore, must be interpreted in light of plausible physical mechanisms. Dr. Hill concluded by expressing his hope that the dialogue begun at this symposium will continue.

In his summary remarks, Dr. London stated that there seem to be no serious objections to the statistical methods used. It is only the conclusions that are questioned, on the grounds that (1) the length of record was probably too short to eliminate low frequency effects of meteorological variabilities, (2) there may be systematic long-term trends affecting the observational system (giving incorrect data variations), and (3) stations chosen for the trend may not be representative of their geographic area and, therefore, would not give a correct global average.

Summarizing the suggestions offered during Session III, Dr. London underscored the recommendation that the same statistical methods be applied to meteorological data for which there are long, compatible series (e.g., temperature, precipitation, drought index, etc.) and where known trend changes have taken place (e.g., change from Northern Hemisphere warming to cooling around 1940). A second suggestion was that further research and data "washing" be done to make the various observational series homogeneous. The effects of optical wedge deterioration, atmospheric aerosol variation, solar irradiance variation, etc., need to be evaluated with more precision than has been done so far. "It should be emphasized that the importance of the problem dictates that reasonable sums of money must be expended to support this type of research." Finally, referring to the geographic representativeness of the data, Dr. London emphasized that a coupled satellite ground-based observational system is required to determine global long term trends. This requires maintenance and improvement of the Dobson network and long term planning for a satellite observing system.

Dr. London concluded by thanking the NASA sponsors, in particular Dr. Greenwood, for convening the Symposium, and the attendees who took time from their busy schedules to participate.

Dr. Greenwood also thanked the attendees and suggested that the participants send him their comments and/or recommendations after they have had time to reflect on the discussions. "A role that NASA can play is to encourage a continuing dialogue and we are open to suggestions on how best to do this."

TOTAL OZONE TREND SIGNIFICANCE FROM SPACE AND TIME VARIABILITY OF DAILY DOBSON DATA

Robert W. Wilcox

Research Division, Control Data Corporation
Minneapolis, MN

Abstract

Assessing the significance of apparent total ozone trends is equivalent to assessing the standard error of the means. Standard errors of time (area) averages depend on the temporal (spatial) variability and correlation of the averaged parameter. Trend detectability is discussed, both for the present network and for satellite measurements, using statistics from daily observations at Dobson stations from 40° and 60°N.

1. Introduction

For several years much interest has been attached to detection of possibly anthropogenic trends in total ozone, either at single stations or station groups. Significance of trends or, equivalently, the standard errors of point- or area-means, is properly derived from knowledge of variances and of data independence, i.e., knowledge of temporal and spatial autocorrelations (e.g., Lieth, 1973; Jones, 1975). In general, authors who report ozone trends (e.g., Angell and Korshover, 1973, 1976; Komhyr et al., 1971, 1973; London and Kelley, 1974; Hill et al., 1975, 1977) use only monthly mean data, and are not explicit about how they assessed the standard error of the monthly averages, or, where used, of the area averages. The purpose of this note is to present estimates of standard errors of total ozone time and area means, as derived from ozone's natural temporal and spatial variability and autocorrelation in middle latitudes determined from daily Dobson data. The use of this information in assessing detectability of total ozone changes, at single stations and over areas, will be demonstrated.

2. Method

a. Data. Daily total ozone data for each of 26 Dobson stations between 40° and 60°N for the period 1957-1972 were obtained from the World Data Center for Ozone, Toronto, and were checked for gross errors before processing. For our purposes, a trend is defined as a change, of time scale at least one year, which is not explained by deterministic variations. Trends must be detected against a backdrop of non-deterministic variability, and a primary task is to describe this variability. In order to do this, the mean, a trend over the entire period-of-record, an average 29-month quasi-biennial oscillation, and the first three harmonics of the annual variation were subtracted from the data (see Wilcox et al., 1977) and the study proceeded using the residuals. These residuals primarily contain a somewhat persistent ("reddish") synoptic scale variability, but with assumed "white" contributions from smaller scale processes and from observational error. Any unremoved deterministic periodicity will increase the correlations, but this effect is thought to be quite small. The residuals are undoubtedly more seriously affected by slow calibration drifts and by changes in wavelengths used, and there needs to be a comprehensive, continuous program to check calibrations and observation techniques, as well as to recompute published values as necessary. The subtracting of a trend from the data can help remove slow calibration drifts, and it is hoped that any remaining non-random observation error is relatively small.

b. Standard error of time averages. For an atmospheric variable whose autocorrelation, R , is approximated by a "red-noise" model $\hat{R} = \exp(-b\tau)$, where τ is lag, Lieth (1973) has shown that

$$\frac{\sigma_T^2}{\sigma^2} = \frac{2}{bT} \left\{ 1 - \frac{1}{bT} [1 - \exp(-bT)] \right\} \quad (A1)$$

Here, σ_T is the standard error of the mean, σ the standard deviation of the unaveraged time series, and T the averaging interval.

To find this ratio for total ozone, correlations at lags from 1 to 16 days were computed from the residuals for the four seasons (winter is December through February). "Zonal mean" correlation coefficients were estimated by weighting the station correlation coefficients by the square root of the number of observation pairs at that station relative to the total pairs of all 26 stations. The resulting correlation coefficients for lags 1-7 days are shown in Fig. A1. The average number of pairs for any lag at a station was 465 in winter and slightly larger in the other seasons. For the purpose of assessing the significance of the zonal mean autocorrelations it is estimated that, of the 26 available stations, nine are independent (more on this in the next section). Effectively, then,

Figure A1. Total ozone temporal autocorrelations, zonally averaged, from the Dobson stations between 40° and 60°N, for lags 1 to 7 days.

we have about 4200 pairs at each lag, which implies that any "zonal mean" correlation coefficient above about 0.04 in absolute value is significant at the 99% level.

The computed coefficients for lags 1-5 days were fitted with the simple red-noise model $\hat{R}(\tau) = a_\tau \exp(-b_\tau \tau)$. The coefficients a_τ and b_τ , for each season, are shown in Table A1. The "zonal mean" τ temporal standard deviations, both day-to-day, σ_d , and year-to-year, σ_a , were also obtained by weighting the variances at stations by the square root of the number of observations.

The difference of a_τ from unity is mostly due to observation error (see e.g., Julian & Thiebaux, 1975), and the value $\sigma_\epsilon^2 = \frac{1}{2} (1 - a_\tau^2) \sigma_d^2$, whose square root is given in Table A1, may be interpreted as variance due to observation error. Therefore, σ_d^2 reduced by this amount is σ^2 , the "true" day-to-day variance. Using the values of b_τ from Table A1, equation (A1) yields $\sigma_T/\sigma = .21, .21, .21$, and $.22$ for winter, spring, summer, and fall, respectively (90-day means). For example, a single winter season average at a typical mid-latitude station will have a standard error (from the true season mean) of $.21\sigma$, or 8.2 D.U. Calculations for other averaging times and/or seasons can easily be made.

It is a well-known result of sampling theory that

$$\sigma_T^2 = \sigma^2/N \quad (A2)$$

where N is the effective sample size. Since the asymptotic value of σ_T^2/σ^2 , from equation (A1), is $2/b_\tau T$, the effective sample size $N = T/T_0$ where

$$T_0 = \int_{-\infty}^{\infty} R(\tau) d\tau = 2/b_\tau \quad (A3)$$

is a characteristic time between effectively independent observations (Lieth, 1973). Values of T_0 are shown in Table A1.

c. Standard error of area averages. The preceding method may also be applied to the determination of errors in spatial averages and equation (A1) again applies, with T now understood to refer to an averaging distance. Correlation coefficients of nearly simultaneous residuals at different stations were computed, and, in order to include large lags while keeping some uniformity in the data set, pairs were restricted to those whose orientations were more east-west than north-south. Figure A2 shows these correlation coefficients (to save space, only those pairs whose longitude separations are 90 degrees or less are shown). Similar computations have been made by Fabian (1967) for a set of European Dobson stations and by Nastrom (1977) for aircraft measurements of ozone concentration near the tropopause.

Table A1. Total ozone temporal variability and correlation statistics, zonally averaged, from Dobson stations between 40° and 60°N.

Season	Model $\hat{R} = a_{\tau} e^{-b_{\tau} \tau}$		"Day-to-day" standard deviation	"Year-to-year" standard deviation	observation error	σ_d corrected for obs. error	Time between independent observations
	a_{τ}	b_{τ}	σ_d	σ_a	σ_{ϵ}	σ	T_o
Dec-Feb	.940	.490	40 D.U.	15 D.U.	9.7 D.U.	39 D.U.	4.1 days
Mar-May	.856	.470	36	11	13.1	34	4.3
Jun-Aug	.812	.493	22	9	9.2	20	4.1
Sep-Nov	.880	.448	25	9	8.4	23	4.5
Annual Average	.872	.475	31	11	10.1	29	4.3

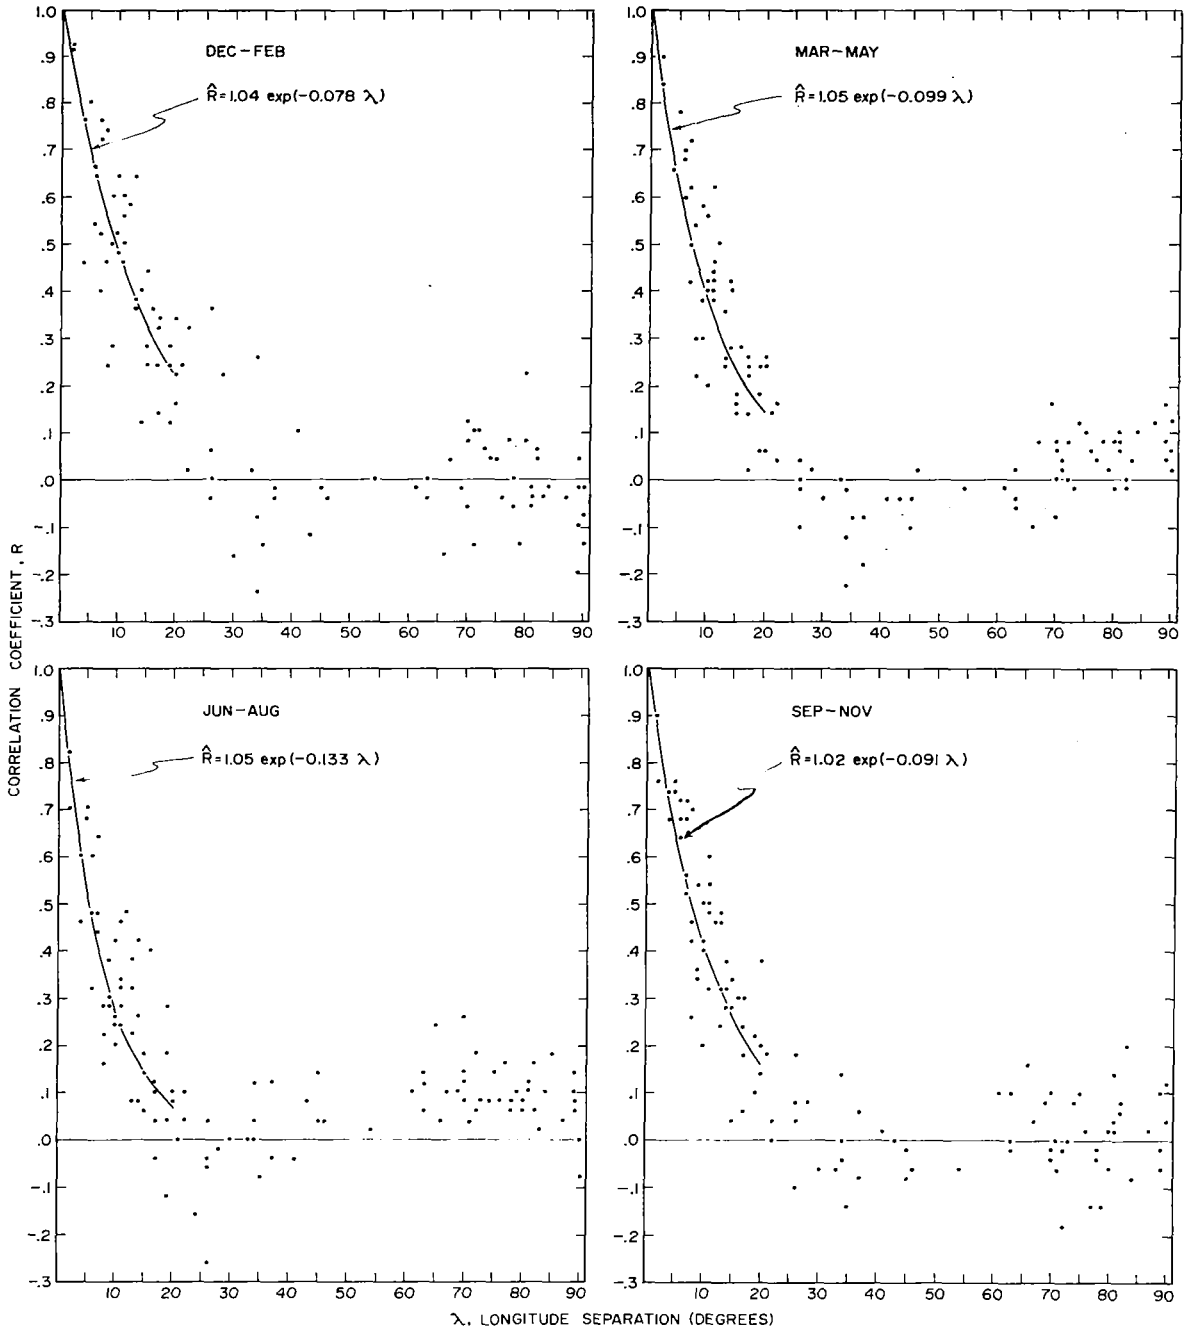

Figure A2. Total ozone spatial autocorrelations for separations (lags) 0 to 90 degrees longitude. Only Dobson stations between 40° and 60°N were used, and the pairs were restricted to those whose orientations were more east-west than north-south.

An average of about 400 observation pairs goes into each correlation coefficient in Figure A2. However, the autocorrelation within the time series at each station affects the significance of the cross-correlation between the two stations. Mitchell's (1963) approximation for effective sample size using purely persistent series implies that a correlation coefficient must be above about 0.18 in absolute value to be significant at the 99% level.

The red-noise model $\hat{R} = a_{\lambda} \exp(-b_{\lambda} \lambda)$, where λ is longitudinal separation (lag), was fitted to various sub-interval averages of the measured correlations from the range of lags 0 to 20 degrees. In computing the sub-interval averages, the individual correlations were weighted by the square root of the number of observation pairs. The time difference between observations at both stations of a pair was generally less than about 2 hours for these small separations, and the associated temporal variability was neglected. (Note that the taking of sub-interval averages effectively lowers the 0.18 significance threshold somewhat in the range 0-20.) The values of a_{λ} being generally greater than 1 indicates that a better model would have used λ raised to a power slightly greater than 1; however, this refinement in the present study does not seem warranted. Inserting values of b_{λ} in equation (A1) yields, for zonal means, $\sigma_T/\sigma = .26$, .23, .20, and .24 for winter, spring, summer, and fall respectively. Application of these results will be demonstrated presently.

An effective length between independent observations, $L_0 = 2/b_{\lambda}$, is also given in Table A2. These values were used in subjectively estimating, in the previous section, that of the 26 available stations only about 9 were independent. Extrapolation would indicate that on the order of 100 effectively independent daily values are possible from an ideal global network.

Table A2. Total ozone spatial variability and correlation statistics, zonally averaged, from Dobson stations between 40° and 60° N.

Season	Model $\hat{R} = a_{\lambda} e^{-b_{\lambda} \lambda}$		Longitude separation of independent observations L_0
	a_{λ}	b_{λ}	
Dec-Feb	1.04	.078	26 deg
Mar-May	1.05	.099	20
Jun-Aug	1.05	.133	15
Sep-Nov	1.02	.091	22
Annual Average	1.04	.100	21

3. The significance of point- and area-average total ozone trends.

A common method for determining trends uses monthly or seasonal deviations from the long-term normal (e.g., Angell and Korshover, 1973, 1976; Pittcock, 1974; London and Kelley, 1974). Significance of single station trends is determined by the size of the standard error of these deviations, which can now be determined from equation (A1), using $T = 30$ or 90 days, and σ from Table A1. If long-term means are required, the problem is only slightly different. Here, it seems reasonable to assume that little interannual correlation exists in the residuals (e.g., Hill et al., 1975), except possibly for a small amount due to a sunspot cycle. Therefore, the standard error σ_{LT} of a long-term seasonal (90-day) mean as an estimate of a climatic mean is given by equation (A3) substituted in equation (A2), i.e.,

$$\sigma_{LT} = \frac{b_{\tau}(\sigma^2 + \sigma_a^2)^{1/2}}{2(90Y)} \quad (A4)$$

where Y is the number of years considered, and the inclusion of σ_a accounts for the effect of interannual variability.

Several authors (e.g., Angell and Korshover, 1973, 1976) compute means at groups of stations in order to estimate regional trends. To determine the standard error of such group means, one must account for both the temporal and spatial correlation. To fix ideas, consider the standard error of a group mean for several stations which can all be conveniently enclosed in a rectangle whose sides are lengths L_1 and L_2 . The standard error of the seasonal mean at each of the stations is given by equation (A1), and as a first approximation we will consider that the mean at every point within the area is known within the same standard error. This is an optimistic view, but one which becomes more realistic as station density increases. To account for the spatial averaging, it is appropriate to apply equation (A1) using b_{λ} with $T = L_1$, and then apply it again using $T = L_2$. This assumes isotropy, which again is probably valid only to a first approximation (see, e.g., Buell, 1972; Julian and Thiebaux, 1975). Note also that the spatial standard deviation of the (instantaneous) field of total ozone is now required. This computation has not been carried out; however, oscillations in the residuals are likely due predominantly to truly transient eddies, and thus will affect all stations in the latitude band more or less equally. This being the case, the temporal standard deviation should be a reasonable approximation of the spatial standard deviation.

As an example, the standard error of yearly means for the group of North American stations between 40° and 60°N will be estimated (Churchill, Edmonton, Goose Bay, Caribou, Green Bay, Bismark, Bedford, Fort Collins, Boulder, and Toronto). Using the "zonal mean"

statistics which are already given in Table A1 (instead of a set derived specifically from these stations), $\sigma_T/\sigma \approx 0.11$. The longitudinal extent of this area is about 40 degrees, while the latitudinal extent is about 17 degrees, or roughly equivalent to 26 degrees longitude. Using equation (A1), these values of T yield ratios $\sigma_T/\sigma = .61$ and $.70$ respectively, and the result if $\sigma_T = (.11 \times .61 \times .70)\sigma = .047$ (29) ≈ 1.4 D.U. In other words, a detected $2\sigma_T$ (i.e., 2.8 D.U.) change from one year to any other year in the annual mean total ozone in this region could be judged significant at the 95% level of confidence.

4. Concluding remarks

It has been shown that standard errors of the mean for time- and space-averages are properly determined from time and space correlation and variability statistics. Sample statistics have been given, on a seasonal and zonal mean basis, for the Dobson stations between 40° and 60° N. Further research in this vein should aim at determining these statistics for all the specific regions and years where Dobson measurements are available. Also, since anisotropy is expected, the north-south statistics should be included.

Hill et al. (1977), have assessed the detectability of global total ozone trends at about 1%, assuming an (independent) 18-station network. The present work suggests that there probably exist at least that many stations whose monthly means are independent (but see Pittock, 1974). However, Hill et al., apparently assume that these 18 determine the means (to within the same standard error) at all points on the globe. This does not seem likely, as has been previously stated implicitly by Kohmyr et al. (1971); Pittock (1974); and Angell and Korshover (1976). However, the example in the preceding section points to the likelihood that trends can be calculated with high confidence for certain areas of high station density, such as the United States and southern Canada, Europe, and perhaps India and Japan. Trends over regions not presently well-sampled will apparently only be detected by future satellite observations of total ozone. Note that the assumption that one knows the mean to within the same standard error at all points within a region is well-satisfied with satellite observations. It is thus of some interest to determine, a priori, the space and time scales of averaging required to detect a change in ozone with a given level of significance from satellite observations. For example, let it be necessary to detect a regional 1% change in annual mean total ozone (i.e., 3.5 D.U.) at the 99% significance level. Such a confidence level requires that $2.6\sigma_T < 3.5$ D.U., or $\sigma_T \leq 1.3$ D.U. Averaging over a year (with $b_T = .475$ and $\sigma = 29$) yields $\sigma_T = 3.1$ D.U. In addition, averaging over a square 3000 km on a side would decrease σ_T/σ by another factor of $(.60)^2$ to $\sigma_T = 1.1$ D.U., thus satisfying the requirement. Such preliminary

estimates of trend significance are important in the planning of observing programs. However, several years of satellite observations will have to be available before year-to-year changes can be recognized as either part of some periodicity or not.

Acknowledgments

The author is grateful to Dr. A. D. Belmont and Mr. G. D. Nastrom for helpful suggestions.

16. Abstract <p>The NASA-sponsored Symposium on Ozone Trend Detectability afforded atmospheric scientists and statisticians the opportunity to exchange information related to the nature of available ozone data and techniques used to detect long-term trends. Specifically the attendees addressed the questions of how quickly and at what level scientists can detect anthropogenic changes in the ozone shield, and whether there is any empirical evidence of the predicted depletion in total ozone. The first session dealt with the nature of available data, with particular emphasis on factors influencing the measurement accuracy and precision. The second session treated analytical/statistical trend detection techniques which have been applied to the data and the results of these applications. Three issues were identified in subsequent discussions: (1) the predictability of climatological series, (2) whether empirical models can be trusted to provide physical insight, and (3) how the accuracy and precision of ozone measurements affect trend detectability. In particular recommendations were made to identify and quantify, if possible, serious error sources and either eliminate them or correct for their presence. Other recommendations involved the careful review of Dobson data to make the best use of this resource for finding trends, the inclusion of appropriate exogenous variables into ozone models to account for natural variability, and modification to the time series models used for trend analysis.</p>
